Printing and Publishing.—Contrary to a not uncommon belief, the business of publishing periodicals is quite distinct from printing them. Not all publishers are printers any more than all printers are publishers. I mention this to show that the business of publishing a technical journal is somewhat intangible, consisting essentially of an organization having three definite objects—first, to produce a journal which readers will subscribe for; second, to obtain a circulation which makes the advertising space valuable to manufacturers in its field; and third, to secure advertising patronage from the manufacturers in the field which the journal represents. This is the logical order in which these different departments of the business should be placed, but frequently inexperienced publishers endeavor to reverse the order, putting the advertising first and the circulation last. Advertising is necessary for any periodical under present conditions, and the advertising income is more than three-quarters of the total. The subscription income is barely sufficient to pay for the white paper and postage.

But though I have placed the editorial function, that is, the collection and presentation of suitable reading matter in the first place it is really one leg of the tripod on which a publishing business is supported. The reading matter is that which gains and holds a paid circulation among the men to whom the ... not bring returns; and without advertising patronage the modern trade journal can not be maintained.

Very apt expressions.

Value of the Reading Pages.—For the sake of emphasis we will expand a little in following around the circle of relative value. It is the circulation of a paper which gives the advertising pages their value, and it is the reading pages which maintain that circulation, although we are not unmindful of the fact that a paper may be of little value, or it may contain no matter at all, and still have a circulation. There is a vast difference, however, between a paper containing high-grade technical matter and one having little or no material that would interest an engineer, superintendent or foreman. One is creative, the other a drone in the hive; one educates and contributes much toward mechanical development by the interchange of ideas between superintendents, designers, foremen and machinists, whereas the other is a non-producer and contributes nothing. The real value of a mechanical journal, then, can be gaged to a large extent by the educational value of its reading pages, because the demand for modern equipment is directly proportional to the knowledge possessed by those who are to use the equipment. A journal without interesting reading pages has no backbone. What that means is clearly stated in the little girl's definition: "The backbone is something that holds up the head and ribs and keeps one from having legs clear up to the neck."

Technical Advice.—Every technical journal acts in an advisory capacity ...

Good. Believe we all like humor even in technical reading.

... our work of greater usefulness we have recently retained a well-known engineer in a consulting capacity to advise upon those technical matters in which he is especially proficient. I mention this to show you what our conception is of the relation of a trade or technical journal to its readers.

While it may be that the problems that stump you will also stump the editor unaided, remember that he is in close touch with an army of men—machinists, toolmakers, draftsmen, engineers, superintendents and others—who are up against almost every conceivable problem in the world of mechanics. Your mechanical perplexities turned into the editorial sanctum will act as suggestions, if nothing more, for articles and editorials on subjects of timely and vital interest. You probably know that the mechanical journals receive many more contributions ...

What a God-send to the one isolated from his fellows to be able to get in touch thru the editor.

Yes why? An auto enthusiast asks why auto builders don't get together, test out various devices, determine which are best and standardize them instead of each advertising his device as best.

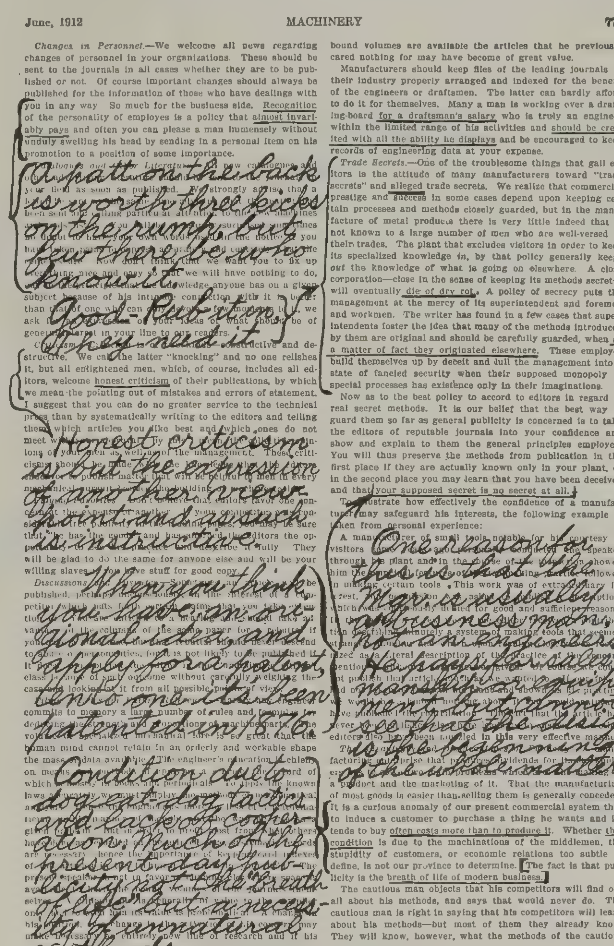
... has planned for that which certain ones of you will furnish. Now why can there not be established an understanding between groups of machine tool builders to the end that they will advertise in harmony, having in mind certain combinations of equipment, which are most often specified? Take, for ex-

* Paper read before the semi-annual convention of the National Machine Tool Builders' Association, Atlantic City, N. J., May 16-17.
† Editor of MACHINERY.

The user of course foots the bill, in the ultimate, for this needless antagonism.

A scythe is whetted by a stone, but man's intellect is best whetted by contact with other intellects similarly trained and interested. You may be marooned on an intellectual oasis, as far as personal contact is concerned, yet you have freedom of expression and response through the technical press ever at your command. The main trouble is that you do not take advantage of your opportunity. You have a right to renew or discontinue your subscription just as the fancy strikes you, but you do not realize that you also have a right to suggest ways and means for making the magazine what you would have it.

It is a joy and stimulus to a writer to know that his articles have been carefully read. Comment and criticism thereon



June, 1912 MACHINERY 777

Changes in Personnel.—We welcome all news regarding changes of personnel in your organizations. These should be sent to the journals in all cases whether they are to be published or not. Of course important changes should always be published for the information of those who have dealings with you in any way. So much for the business side. Recognition of the personality of employes is a policy that almost invariably pays and often you can please a man immensely without unduly swelling his head by sending in a personal item on his promotion to a position of some importance.

A patt on the back is worth three kicks on the rump, but few there be who know it.

Good—Rub it in. They need it.

Criticism.—Criticism is of two kinds—constructive and destructive. We call the latter "knocking" and no one relishes it, but all enlightened men, which, of course, includes all editors, welcome honest criticism of their publications, by which we mean the pointing out of mistakes and errors of statement. I suggest that you can do no greater service to the technical press than by systematically writing to the editors and telling them which articles you like best and which ones do not meet with your approval ...

Honest criticism is but the expression of another viewpoint and as such is instructive.

... They will be glad to do the same for anyone else and will be your willing slaves if you have stuff for good copy.

When you think you have an original idea, and apply for a patent, ten to one it's been patented in 1876.

Condition due to dog-eat-dog tactics and lack of cooperation. Much of the present day publicity not the "breath of life" but a necessity of unnatural methods.

bound volumes are available the articles that he previously cared nothing for may have become of great value.

Manufacturers should keep files of the leading journals in their industry properly arranged and indexed for the benefit of the engineers or draftsmen. The latter can hardly afford to do it for themselves. Many a man is working over a drafting-board for a draftsman's salary who is truly an engineer within the limited range of his activities and should be credited with all the ability he displays and be encouraged to keep records of engineering data at your expense.

Trade Secrets.—One of the troublesome things that gall editors is the attitude of many manufacturers toward "trade secrets" and alleged trade secrets. We realize that commercial prestige and success in some cases depend upon keeping certain processes and methods closely guarded, but in the manufacture of metal products there is very little indeed that is not known to a large number of men who are well-versed in their trades. The plant that excludes visitors in order to keep its specialized knowledge *in*, by that policy generally keeps *out* the knowledge of what is going on elsewhere. A close corporation—close in the sense of keeping its methods secret—will eventually die of dry rot. A policy of secrecy puts the management at the mercy of its superintendent and foremen and workmen. The writer has found in a few cases that superintendents foster the idea that many of the methods introduced by them are original and should be carefully guarded, when as a matter of fact they originated elsewhere. These employes build themselves up by deceit and lull the management into a state of fancied security when their supposed monopoly of special processes has existence only in their imaginations.

Now as to the best policy to accord to editors in regard to real secret methods. It is our belief that the best way to guard them so far as general publicity is concerned is to take the editors of reputable journals into your confidence and show and explain to them the general principles employed. You will thus preserve the methods from publication in the first place if they are actually known only in your plant, or in the second place you may learn that you have been deceived and that your supposed secret is no secret at all.

To illustrate how effectively the confidence of a manufacturer may safeguard his interests, the following example is taken from personal experience:

One reason for this is that the Mgr. is usually a business man, not an engineer. He pays for salesmanship or equipment but cannot see that the design is the beginning of the whole matter.

... a product and the marketing of it. That the manufacturing of most goods is easier than selling them is generally conceded. It is a curious anomaly of our present commercial system that to induce a customer to purchase a thing he wants and intends to buy often costs more than to produce it. Whether this condition is due to the machinations of the middlemen, the stupidity of customers, or economic relations too subtle to define, is not our province to determine. The fact is that publicity is the breath of life of modern business.

The cautious man objects that his competitors will find out all about his methods, and says that would never do. The cautious man is right in saying that his competitors will learn about his methods—but most of them they already know. They will know, however, what the methods of the cautious

spur him to further effort and put him in touch with his readers' viewpoints. If you cannot write a good article yourself, you can offer intelligent comment in the manner indicated, and will find that such mental exercise is good for you—it will teach you to read appreciatively.

* * *

NEW METHOD OF GALVANIZING IRON

A description of a new method recently patented of galvanizing iron is quoted in the United States *Daily Consular and Trade Reports* from a German publication substantially as follows: To protect iron objects from rust it is customary to coat them with zinc, deposited either electrolytically or by plunging them in a bath of melted zinc. The disadvantage of these methods is that real fusion of the two metals is not obtained, and as a result the zinc coating does not properly protect the iron surface underneath. The defect is avoided by the new process which consists in so preparing the iron that the zinc is intimately associated with the surface of the iron, being deposited into its pores. After steeping the parts to be coated in sulphuric acid, they are placed in a solution of mercuric chloride, and then heated, resulting in the decomposition of the mercuric chloride and precipitation of metallic mercury which forms an amalgam on the surface. The iron is then plunged into a zinc bath heated to 500 degrees F., where it remains three minutes. The zinc coating deposited by this method adheres very strongly to the metal. Microscopic investigation shows that the zinc penetrates into the pores of the iron, and in case a portion of the coating is worn or peeled off, the iron does not rust owing to the presence of sufficient zinc in the surface to protect the metal from the action of the atmosphere. In other words, there is a perfect alloy or association of the two metals at the point of juncture.

SAFEGUARDS FOR POWER PRESSES*

A NUMBER OF EFFECTIVE SAFETY DEVICES ADOPTED BY LEADING MANUFACTURERS

BY EDWARD K. HAMMOND

The problem of providing for the safety of power-press operators presents two possibilities of solution. The first alternative is to use presses equipped with some form of automatic feeding device that makes it unnecessary for the operator to put his fingers under the ram. The second is to adopt some form of safeguard that keeps his hands away from the die during the working stroke of the ram.

The different forms of automatic feeding devices which have been successfully applied in power-press work were fully discussed in articles published in MACHINERY October, 1911, and January, 1912. Owing to the fact that automatic feeding removes the necessity for the operator to put his hands under the ram, presses equipped with such feeding devices are as safe as they can be made for handling the class of work required of them. These devices do not reduce the operator's output, and the only argument against them is that the first cost of presses equipped with automatic feeding devices is higher.

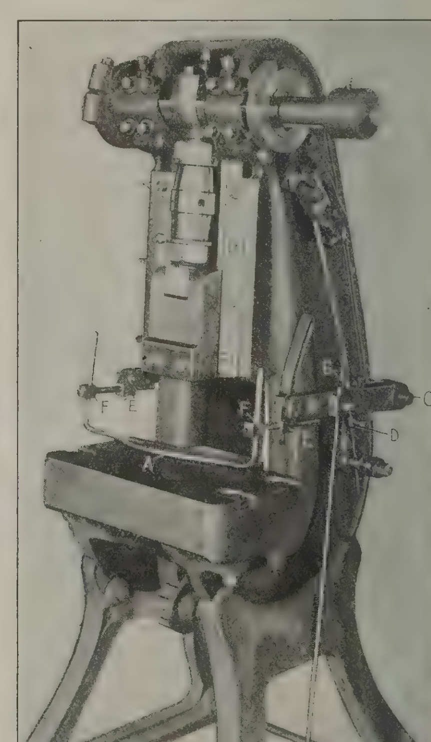

Fig. 6. Safeguard using a Bar instead of Gates

* For further information relating to the safeguarding of machinery and the prevention of accidents in shops and factories, see "Prevention of Industrial Accidents," MACHINERY, engineering edition, April, 1912, and "The Prevention of Industrial Accidents," in the engineering edition, November, 1911. See also the list of previously published matter referred to in connection with the article last mentioned.

In this article, different forms of power-press safeguards which have found successful application in well-known manufacturing plants, will be described. An important advantage in favor of their application lies in the fact that they can be used on the presses which a shop already has in operation, thus providing for the safety of the operator at a relatively small expense. Among the different types, one can almost always be found which will meet the requirements of any one class of power-press work.

The advisability of adopting every precaution to provide for the operator's safety offers little ground for discussion. Aside from humanitarian considerations, which constitute a sufficient reason, safeguards are well worth while when considered from a purely economic standpoint. The premiums charged for accident insurance for operators of power presses average about eight times the rates for operators of other classes of metal working machinery. Well designed safeguards reduce the risk involved and enable a considerable saving to be made in the cost of accident insurance.

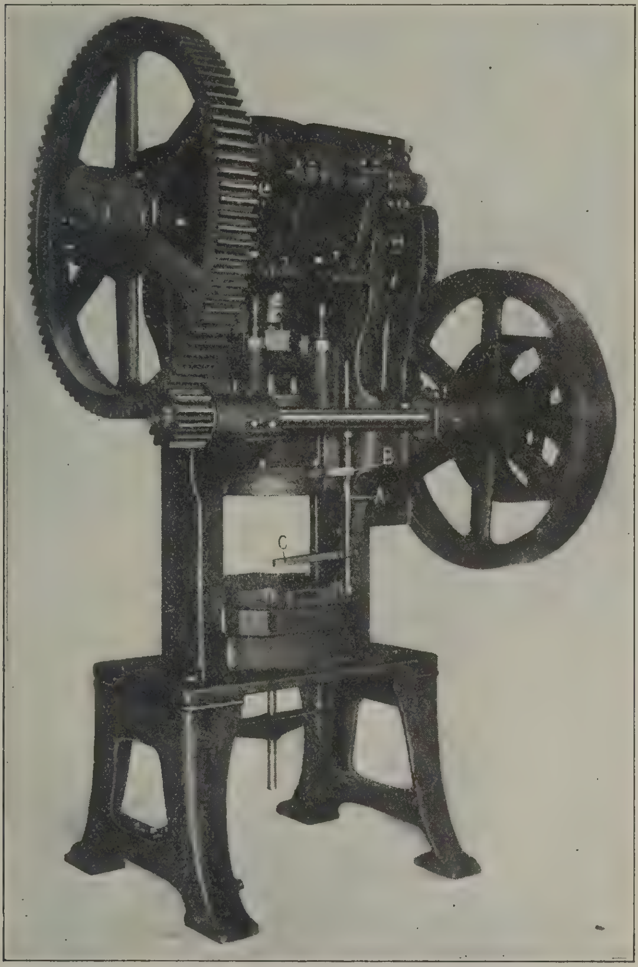

Fig. 7. Guard Bar swung over Die by a Twisted Rod

The Cream City Accident Preventer

The safeguard illustrated in Fig. 1 is manufactured by the Geuder, Paeschke & Frey Co., Milwaukee, Wis. In the manufacture of tinware and sheet steel ware, this company experienced great trouble from the injury of power press operators, and as the result of study given to the subject, the guard shown in Fig. 1 was developed. The original idea was merely to avoid power press accidents in the company's shops, but the guard was found to give such satisfaction that it was decided to place it upon the market. It is known as the "Cream City accident preventer," the first two words corresponding with the names of this company's other products.

The guard consists of an expanding gate, of the pantograph type, which opens before each down-stroke of the ram, thus blocking the approach to the die. It is attached to the press by means of two brackets A, which are secured to the press by means of the regular gib screws. The method of operation is entirely automatic. A lever B is fulcrumed to the side of the press where the driving clutch is located, and is connected with the treadle by means of rod C. When the treadle is tripped, this rod pulls down the lever, which, in its turn, expands the gate in advance of the descent of the ram. The guard is arranged in such a manner that the gate must be all the way down before the clutch can be engaged. This makes it necessary for the operator to remove his hands from the work before the press can be tripped, and should he attempt to adjust the position of a blank at the last moment—which has been one of the most frequent causes of accidents on unguarded presses—the descent of the gate is checked, thus preventing the engagement of the clutch and the downstroke of the ram. When the treadle is released, the tension of spring D causes the gate to return instantly to the folded position, so that it is out of the way for the next operation.

At the place where lever B is pivoted to the frame of the press, a screw E is provided, which enables the point to which the gate must descend before the clutch is engaged to be adjusted. For most classes of work, this screw is set to bring the gate to within at least 1/8 inch of the table before the clutch is engaged. Such a setting, however, would interfere with sheets that extend out in front of the press, and for such classes of work the gate is set to descend to a point just above the level of the die before the engagement of the clutch can be effected. In such cases, the bottom of the gate is practically in contact with the face of the work; consequently, the same degree of protection for the operator is secured.

The application of this guard does not require the construction of the press to be altered in any way, the only work necessary being that of drilling and tapping holes for the bolts which secure the operating lever B to the frame of the machine. The openings in the guard gate enable the operator to have his work in plain view at all times.

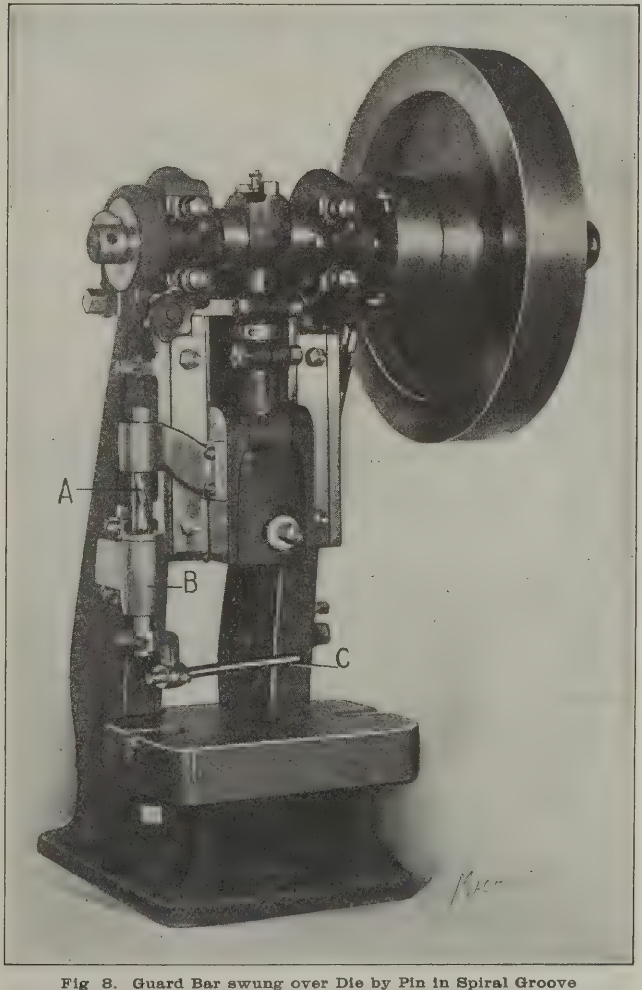

Fig 8. Guard Bar swung over Die by Pin in Spiral Groove

A somewhat similar, although less efficient guard than the one just described, is shown in Figs. 2 and 3. In this case the pantograph gate expands from the side, its movement being controlled by the bar A. As the slide descends, this bar, which is attached to it, engages a cam carried by the pivot

on which lever *B* is mounted. This swings lever *B* down into a nearly horizontal position, as shown in Fig. 2, and expands the pantograph gate across the front of the die, through the leverage exerted by the extended arm *C* of the gate. The action of the mechanism is so timed that the gate shuts off

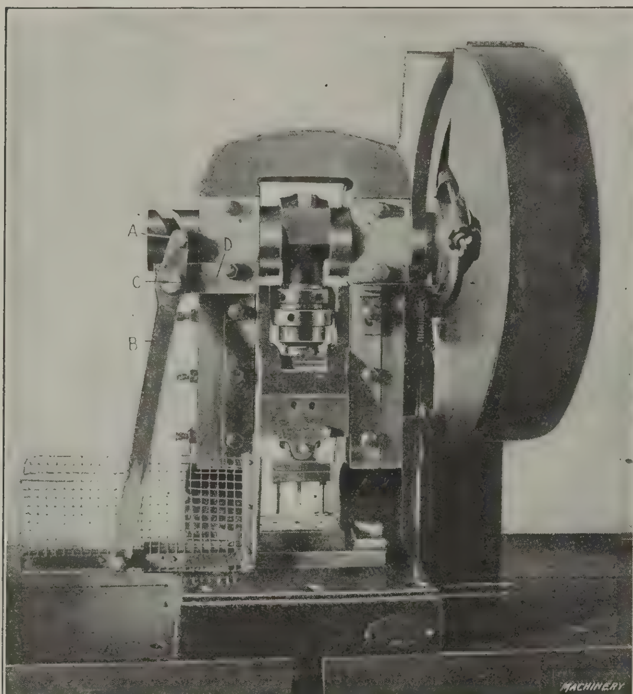

Fig. 9. Safeguard with Gate which swings from the Side

access to the die before the punch has descended upon it. When the ram rises, bar *A* is carried up with it. This releases the mechanism, and the gate is closed by the tension of spring *D*; *E* is simply a guide in which the gate travels.

The Jones Stamping Press Guard

The press illustrated in Figs. 4 and 5 is equipped with a safety device known as the Jones stamping press guard,

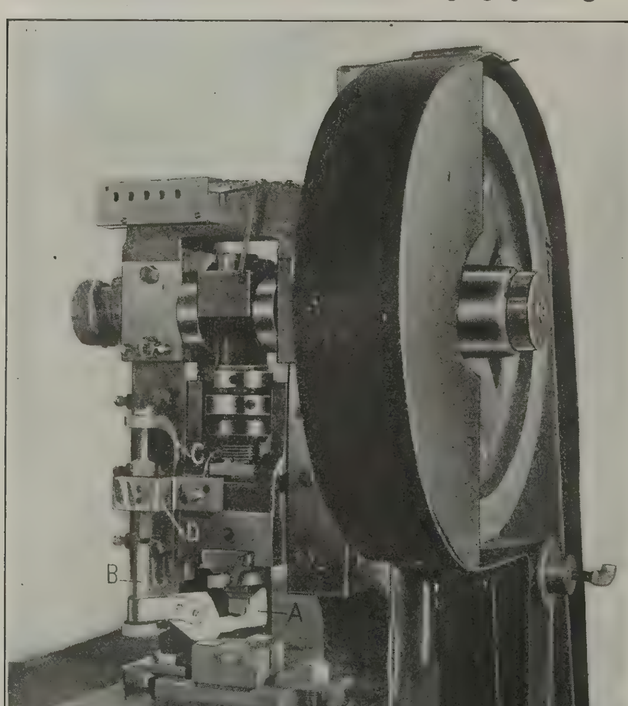

Fig. 11. Guard which sweeps over Die before Ram descends

which is manufactured by the Jones Safety Device Co., Chicago, Ill. When in operation, the wire-mesh gate drops somewhat ahead of the down-stroke of the ram, thus barring the operator's access to the die during the working stroke. The design is such that the gate must reach the bottom of its stroke, which brings it into contact with the table, before the clutch can be engaged.

The operation of the guard is controlled by lever *A*, which is pivoted to the frame of the press. Connection is made

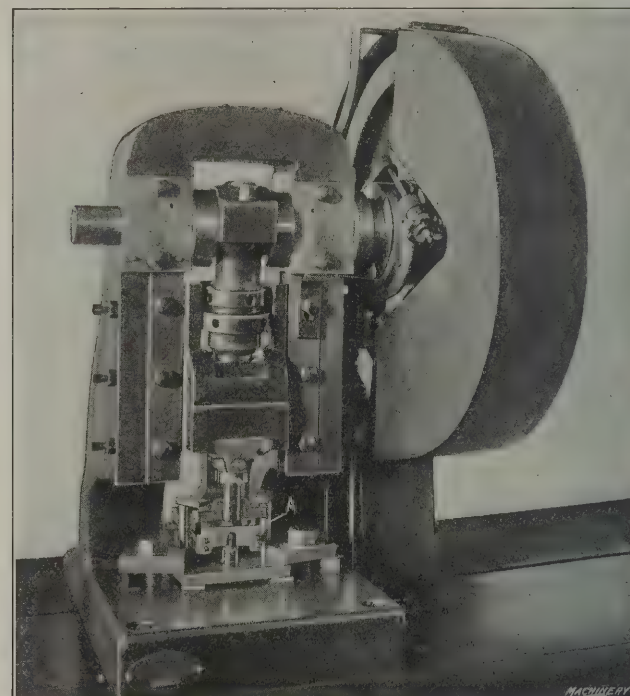

Fig. 10. Guard with a Plate operated by Cam attached to the Ram

between the treadle and the clutch by means of two rods which are secured to this lever by adjustable clips. When the guard is to be applied to an inclinable press, the treadle rod is in two sections, which are threaded at their ends to carry an adjusting clip, so that the length of the rod can be varied as required.

When the treadle is pushed down to trip the press, lever *A*

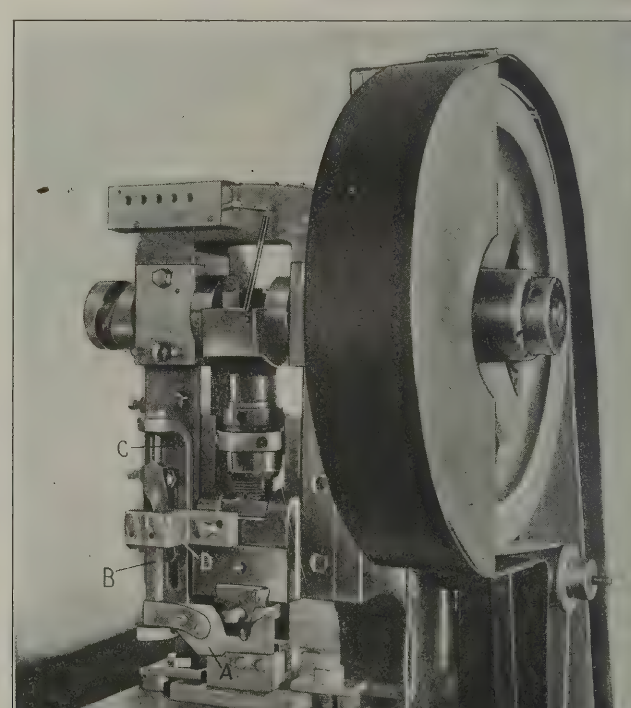

Fig. 12. Same Guard as in Fig. 11, in Position in Front of Die

carries the gate down to the table. If the operator fails to remove his hand from the die, the descent of the gate is blocked and this prevents the press from operating, because the clutch cannot be engaged until the gate has reached the

bottom of its stroke. After the ram has completed its working stroke and started to rise, the gate is immediately lifted by the action of a spring which connects the rear end of lever *A* and the frame of the press. If it is more convenient, this spring can be attached between the treadle and the frame of the machine. The instantaneous action of this spring prevents the output from being reduced, as the guard is out of the way as soon as the ram has risen sufficiently to enable the operator to begin preparing for another operation.

Clip *B*, which secures the gate bar to lever *A*, enables the position of the guard to be adjusted to meet the requirements of different classes of work and dies. The gate should always be set to a point where it touches the table before the clutch can be engaged. This guard is easily attached to the press on which it is to be used. The only work entailed consists of drilling and tapping holes in the frame to secure the operating mechanism in place. In some cases, the wire mesh gate has been replaced by a flat rod, covered with leather, somewhat similar in shape to the one upon which the wire netting is mounted. The object of this modification is to allow the operator an unobstructed view of his work during the entire working period of the press.

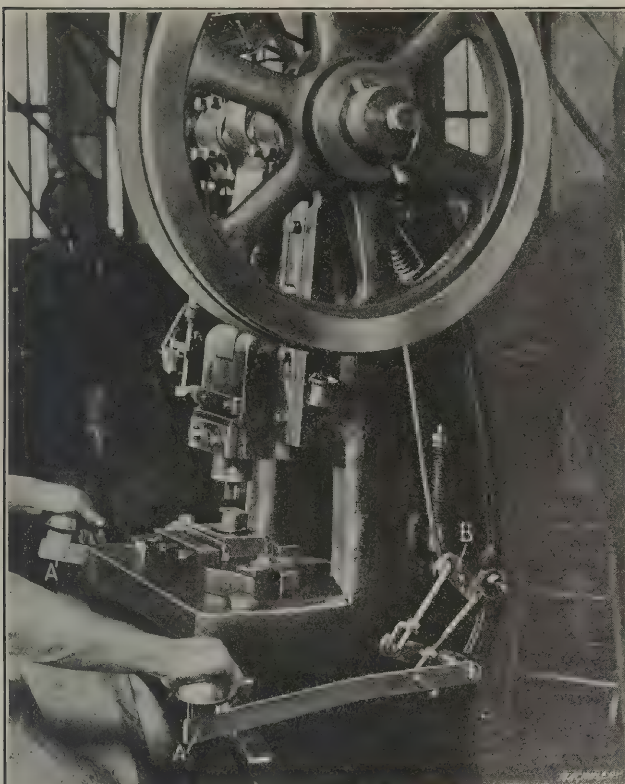

Fig. 13. Arrangement of the Benjamin Stamping Press Guard

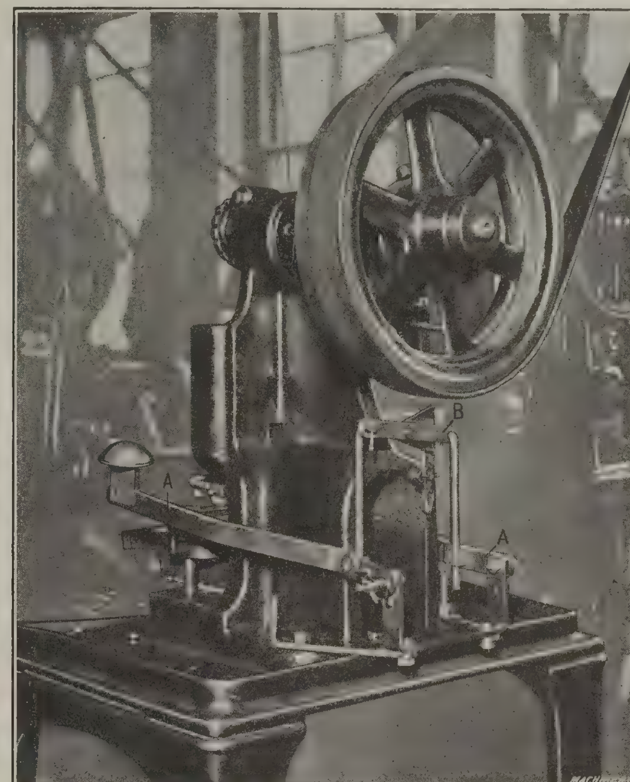

Fig. 14. Another Arrangement of the Benjamin Guard

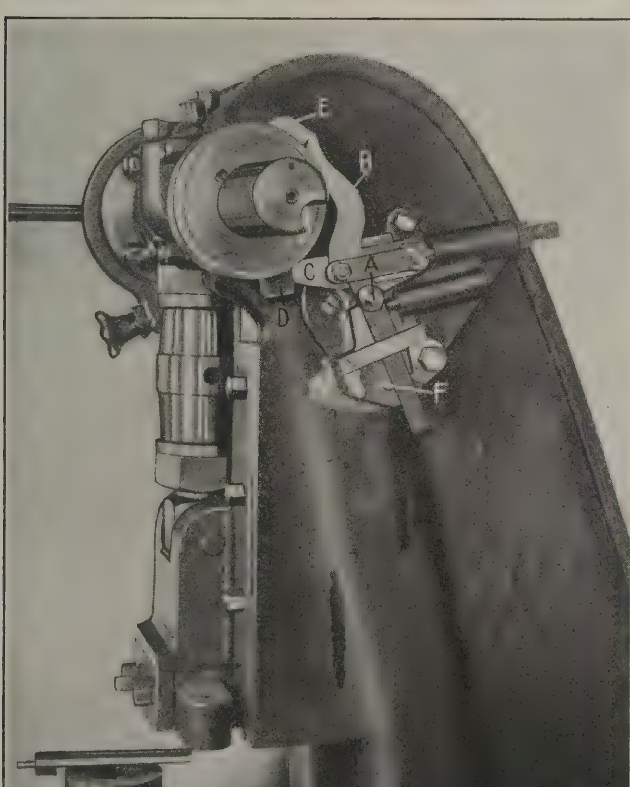

Fig. 15. Mechanism of the Bliss Automatic Safety Clutch

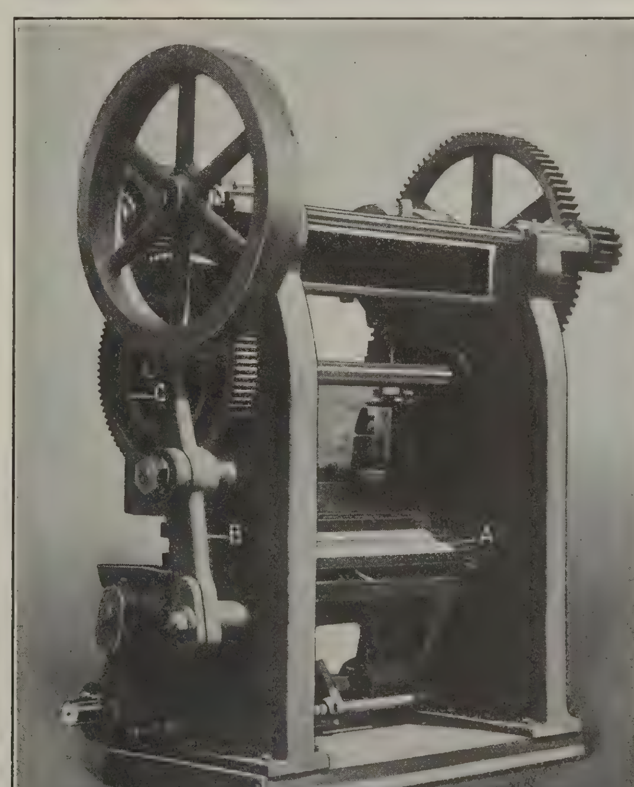

Fig. 16. The Improved Queen City Safety Press

In Fig. 6 a power press guard is illustrated which works on much the same principle that governs the operation of the ones shown in Figs. 1, 4 and 5. In this case, the guard bar *A* has been adopted in place of the gates used in the two other

devices referred to. When an operator is working at a press equipped with one of these guards, his hands are beneath the bar *A* and this bar must drop to the die bed before the clutch can be engaged. This makes it impossible for the operator to trip the press and forget to remove his hands from the die, because, under these conditions, bar *A* cannot fall far enough to allow the clutch to be engaged.

The operation of this guard is controlled by lever *B* which is pivoted to the frame of the press at *C*. When the treadle is depressed, this lever carries the guard bar down with it. After the guard has practically reached the die bed, lever *B* engages the stop *D* on the clutch rod and pushes it down sufficiently to throw the clutch into action.

It will be seen from the illustration that the position of the guard rod can be adjusted horizontally at *E* and vertically at *F*, and that the stop *D* on the clutch rod may be adjusted to correspond with different settings at *F*. This enables the guard to be adapted to different classes of work. The stop *D* should, in all cases, be set so that the clutch cannot be engaged until the guard rod is almost in contact with the die bed.

After the press has been tripped, spring *G* throws the guard up as soon as the ram has begun its return stroke, so that the operator is not delayed in any way. This type of guard can be applied to any type of press without altering its construction, by simply drilling and tapping the holes in the frame of the machine necessary for securing the guard in place.

The two guards shown in Figs. 7 and 8 work on essentially the same principle. When the ram of the machine shown in Fig. 7 begins its down-stroke, the vertical rod *A* is rotated by means of the twisted section which runs through a bearing in *B*. This causes bar *C* to swing over the die, and in case the operator has neglected to remove his hands, they are struck by this bar, thus warning him of his danger. Bar *C* moves considerably before the ram has reached the bottom of its stroke, so that the operator is given plenty of time to get his hands out of danger if he has neglected to do so at the time of tripping the press.

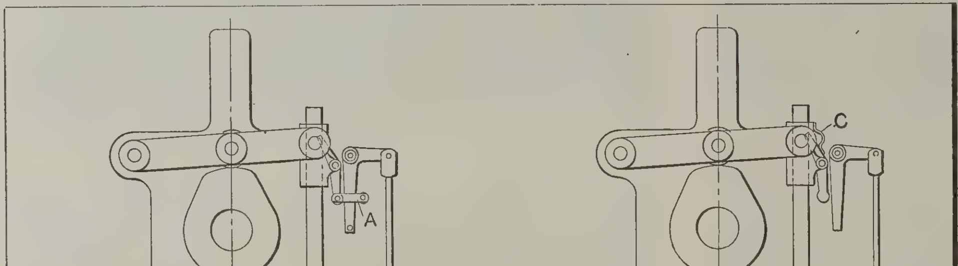

Fig. 17. A Modification of Design, replacing Springs by a Link and Weight

The action of the guard shown in Fig. 8 is similar to that of the one just described, but in this case the round rod *A*, with a spiral groove cut in it, has been substituted for the twisted square rod shown in the preceding illustration. The groove in this rod is engaged by a pin in bearing *B*, thus swinging the guard bar *C* as previously described.

Guards used in the General Electric Co.'s Shops

The guard illustrated in Fig. 9 was developed by the General Electric Co., for use in its power-press shops. When the operator sets the press in motion, the pin which runs in slot *A* swings lever *B* about pivot *C*. The shape of slot *A* is such that lever *B* carries the gate to the right a little ahead of the down-stroke of the ram. This shuts off access to the die during the working stroke of the press; should the operator fail to remove his hands from the work at the time of tripping the slide, he is warned of his danger by the movement of the guard. The gate runs on a guide on the die bed. The guard is secured to the press by bracket *D*, which carries the pivot *C*. This bracket is secured by one of the gib screws and a couple of small pins which prevent it from rotating.

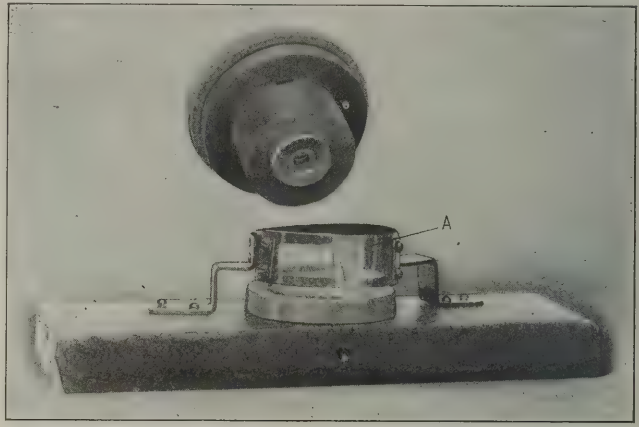

Fig. 18. Guard used for Operations on Thin Stock

Fig. 10 illustrates another form of power press guard which has been used in the shops of the General Electric Co. In this case, the guard plate *A* comes forward, ahead of the down-stroke of the ram, and pushes the operator's hands away from the die. The movement of the guard plate is controlled by a cam attached to the rear of the slide. When the working stroke has been completed and the slide commences its upward travel, this cam releases the guard and allows it to be returned to the rear of the die by the tension of a spring.

The guard illustrated in Figs. 11 and 12 has been adopted by the General Electric Co. to supersede the equipment shown in the preceding illustration. In this case, guard plate *A* swings on rod *B*, passing over the die far enough ahead of the ram to give the operator ample time to get his hands out of danger if he has neglected to do so at the proper time. The guard is attached to the press by means of bracket *C*, which is held in place by means of the regular gib screws. Rod *B* is a loose fit in this bracket, so that it is easily rotated by the action of *D* upon the twisted section of the rod.

When a press is engaged in stamping out parts from thin sheets, a guard of the type shown in Fig. 18 can be used to good advantage. In using a press equipped in this way, the

operator slips the stock under guard *A*. The space between the bottom of this guard and the die is just sufficient to admit the stock, but will not permit the operator's fingers to get within reach of danger. The General Electric Co. uses guards of this type on presses for stamping mica insulations; they would prove equally serviceable on other classes of work where thin stock is being handled.

The Benjamin Stamping Press Guard

The stamping presses illustrated in Figs. 13 and 14 are equipped with a safeguard which has been designed and placed upon the market by the Benjamin Electric Mfg. Co., Chicago, Ill. This device was first developed to meet the requirements of the Benjamin shops, but proved to be so satisfactory that it has recently been placed upon the market. It is not intended for presses used for blanking from strips or ribbon stock, and when presses are used alternately for such operations and for stamping, the guard may be easily disconnected, and the regular treadle used. This change does not involve any particular risk, as blanking operations on ribbon stock do not require the operator to work with his fingers under the ram.

As shown in the illustration, the guard consists of two hand levers *A*, one at each side of the press. These levers connect with the equalizer *B* which is mounted on the clutch rod. This equalizer swings about a pivot at its center, so that pushing down only one of the hand levers does not have any effect upon the clutch. Both levers must be pushed down to trip the press, and as both hands are required for this purpose, the operator cannot get his fingers caught. The release of either lever allows the latch to return to its normal position, thus making it impossible for the press to repeat unless both levers are kept down until the second stroke has been started. In this case, the operator would not have time to get his hand under the ram before its downward travel was completed. Different arrangements of this guard have been worked out to adapt it for use on all standard forms of presses, two such arrangements being shown in the illustrations.

Experience has shown that it is poor policy to depend upon the tension of a spring to control the operation of any mechanism, the failure of which may inflict a serious injury upon the operator. The tension of a spring weakens with age, and may become inadequate for the service which is required of it.

Fig. 17 illustrates a power press that was originally equipped with the springs *C* and *D*, as shown at the right-hand side of the engraving. The danger of relying upon these springs to control the clutch was realized, and the design of the press was modified, as shown at the left-hand side of the illustration. Here link *A* and counterweight *B* have replaced the springs, so that there is no possibility of failure due to an inadequate tension, as the clutch is now controlled by the constant force of gravity.

The Bliss Safety Clutch

A large majority of power-press accidents are caused by the failure of the operator to remove his foot from the treadle after completing an operation. In such cases, the wheel is kept locked to the shaft and causes the ram to descend a second time when the operator is not expecting it. To avoid such accidents, the E. W. Bliss Co., Brooklyn, N. Y., and several other well-known builders of power presses, have designed clutches which require the treadle to first be released and then pushed down again in order to cause the ram to descend for the next operation.

Fig. 15 shows the Bliss safety clutch, which operates in accordance with this principle. When the treadle is pushed down, latch *C* is lowered by means of trip-hook *B*, thus allowing the end of the clutch-key *D* to spring out and throw the clutch proper into position to engage with the flywheel. The shaft now revolves, bringing trip-dog *E* against trip-hook *B*, disengaging it and breaking the connection between latch *C* and the treadle rod that connects at *A*. This allows the latch to spring up and throw the clutch out of action.

When the foot is removed from the treadle, trip-hook *B* re-engages with latch *C*, and the mechanism is ready to be tripped for the next operation. The press may be run continuously by sliding the trip-hook *B* ahead of the spring-pin *F*. In this position, the trip-dog does not strike against the hook, and no break is made between the treadle and the clutch. Consequently, the slide continues to operate as long as the treadle is kept down. The E. W. Bliss Co. is now putting these clutches on all of its presses.

The Improved Queen City Safety Press

The press illustrated in Fig. 16 is built by the Queen City Punch & Shear Co., Cincinnati, O., and has been designed along lines which provide for the operators' safety. The oscillating table *A* swings out from under the ram to permit the removal of finished work and the substitution of new blanks. Hence the operator does not need to put his hands under the ram. The oscillation of the table is controlled by means of rocker arm *B* and cam *C*. The machine shown in the illustration is equipped with a double set of dies and requires two men to operate it, one standing at the front and the other at the rear. After the working stroke, the die bed in which the work has been formed or pressed remains stationary until the ram is partly raised. It then moves forward to the operator and remains at rest long enough to give him ample time to remove the finished work from the dies and replace it with new blanks. During this time, the other die bed is under the ram, a working stroke of the press being made. The die beds thus receive alternate strokes of the press, allowing plenty of time for the operators to perform their work, while the dies are swung out away from the danger zone beneath the ram. Machines of this type are also built with a single die bed and only require one operator to run them.

* * *

LAPPING CRANK-CASES

In the best types of automobile engines, all the vital parts, such as the transmission gears, etc., are enclosed in cases to protect them from dust and dirt. Another point which is just as important as protection from dirt is proper lubrication. In some engines this is accomplished by filling the cases with lubricating oil, which, of course, necessitates that they be oil-tight.

Instead of using packing between the surfaces of the crank- and transmission-cases that come in contact, the White Co.,

Lapping the Contact Surfaces of Crank-cases to make them Oil-tight

Cleveland, Ohio laps all the contact surfaces. This operation is accomplished as shown in the accompanying illustration. A large surface plate is coated with oil and emery, and the cases, after having their contact surfaces milled, are moved back and forth on this plate until a true surface is obtained. This method makes an oil-tight fit which is superior to shims or packing. D. T. H.

DEVELOPING MACHINE TOOLS TO MEET MANUFACTURING CONDITIONS

A well-known machine tool builder, whose product is of a specialized nature, has consistently followed a practice during the past five or six years that undoubtedly has helped greatly in perfecting his machines and selling methods. He took contracts for machining certain difficult pieces in large numbers, submitting prices in competition with other concerns doing contract work. The contracts obtained necessitated equipping a section of his plant on a manufacturing basis to handle this special work. His own machines were installed and fitted with appliances to facilitate the operations as far as possible, after a thorough analysis and time study had been made, and in filling the contracts, workmen were trained to handle peculiar machining propositions with facility and speed never before equalled.

The result was that the limitations as well as the capabilities of his line of tools became apparent as they never had before. Where weaknesses were discovered, the design of the machine was changed to eliminate them, but the most important result was in finding out just how the machine could be used in manufacturing work to the best advantage. This manufacturer now has a corps of salesmen who know exactly what they are talking about and can prove what they claim. They can go into a plant and size up the possibilities of machining almost any given part by their specialized practice, making estimates based on the data acquired in the home plant, and when the machines are installed, operators can be sent to instruct workmen in handling the parts to the best advantage. Consequently guarantees of production can be made and fulfilled that competing makers would not dare to offer.

* * *

THE VALUE OF A PROPER FINISH

A prospective purchaser forms his first impression of a machine largely from its appearance. Sometimes good points in the design are evident at a glance—although this is seldom the case—but whether these points of more intrinsic value show up or not, the care which has been taken in finishing the different parts of the machine contributes much to its appearance and the impression made.

In deciding upon the finish for each part, two points should be considered—the durability of a given finish under the conditions to which it will be exposed in service, and its effect on the general appearance of the machine. The argument is sometimes advanced that an outlay for unnecessary finish adds to the price which the customer must pay for his machines, without giving him any additional value. This is hardly accurate. Shop environment exerts a strong influence upon the ideals of a conscientious mechanic, and he will naturally strive for higher attainments in the quality of his work when it is produced on machines which are well finished.

From the builder's standpoint a good finish is obviously desirable, in that it constitutes an outward manifestation of the quality of the materials and workmanship put into the machine. For instance, where parts are poorly finished because the mechanical operation of the machine does not require them to be accurate, the conclusion naturally follows that the entire machine has been produced with a corresponding lack of care. In this connection, a clearly defined line must be drawn between the substitution of finish for quality in the materials used. The former cannot be regarded in any other light than a deliberate attempt at deception, but a finish that truly represents the quality of the machine, is one of the best means at the builder's command for expressing the care that has been taken in the selection of materials and in the process of manufacture.

* * *

MEASURING SCREW THREADS

Although much has been written on the characteristics of screw threads, screws and taps, and the methods by which they should be measured, it appears that there are many mechanics who are not as well informed on these subjects as they should be. Tap manufacturers constantly receive complaints that their taps are not up to size, when the whole trouble lies in the fact that the users do not know how to measure tap threads properly. Few people realize, it appears, that the outside diameter is of little practical importance, provided it is not under size. A tap is not defective if the outside diameter is considerably over size, provided the pitch or angle diameter is not above the prescribed limit. A tap should always be measured in the angle of the thread, the well-known Brown & Sharpe thread micrometer being the tool most used for this purpose. When using this micrometer, certain precautions must be taken, however, which those unfamiliar with its use are likely to overlook.

A tap manufacturer received several complaints from one of his best customers, that the taps supplied were under size. Now, as a matter of fact, while certain limits are necessary in tap manufacturing, as well as in other fields, no reputable tap maker would ever let a tap go out of his shop that was under size. Taps should always be a certain amount over size, in order to compensate for errors in lead and to provide for a reasonable amount of wear. Some tap manufacturers even instruct their inspection departments to reject taps that are exactly to size, because such a tap, having no provision for compensating for errors in the lead, is practically to be regarded as being under the standard size. Hence the manufacturer of the taps that were said to be under size, doubted the accuracy of the statement, and as the customer who had made the complaint was one well worth taking care of, he went to the latter's plant, several hundred miles distant, to personally investigate the methods and measuring tools used for testing the taps he had supplied. He found that the man who did the testing—apparently a good, all-around mechanic—measured the angle diameter of the threads with a Brown & Sharpe micrometer by holding the tap steadily in one position while he screwed down the micrometer point onto it. When measured in this way the point and anvil are likely to bear upon the surface of the thread at points below or above the actual diameter of the tap thread, so that the true dimension is not obtained, and most of the taps will appear to be below standard size. The angle diameter should be measured by passing the tap back and forth between the point and the anvil of the thread micrometer, so as to make sure that the largest dimension or the actual diameter is being measured. When the taps in question were measured in this way, they were all found to be a certain amount over the standard size, meeting all requirements.

A mistake sometimes is made in measuring threads in the angle with the B. & S. thread micrometer, by using the wrong anvil. The anvil is limited in its capacity to certain sizes of thread, and should agree with the number of threads per inch to be measured. The reason for this is that if made large enough to measure a four-threads-per-inch thread, it would be too wide at the top to measure, say, a twenty-threads-per-inch thread. If, again, it were designed to measure a twenty-threads-per-inch thread it would be so small that a four-threads-per-inch thread would not have a proper bearing in the anvil. Hence each screw thread micrometer is limited to the range of threads per inch that can be measured with the anvil furnished with the tool, and care should be used to employ these micrometers only with anvils designed for the particular numbers of threads per inch to be measured. Otherwise the readings obtained cannot be depended upon.

* * *

WIRE AND SHEET-METAL STANDARD GAGES

The confusion incident to the use of many gages is commonly experienced by all who have to specify wire and sheet metals. We have in common use the American or Brown & Sharpe gage, Birmingham or Stubs iron wire, Stubs steel wire gage, Roebling and Washburn & Moen gage, British Imperial wire gage, U. S. standard gage for sheet and plate iron and steel, Edison or circular wire gage, steel music wire gage, twist drill and steel wire gage and letter drill gage. These gages can be combined so as to give an ascending series differing approximately by thousandths or half thousandths inch, but any one of the standard gages taken by itself will be found to give a large number of sizes varying by small increments at certain stations. Between these stations there are wide gaps that the gage does not provide sizes for. If it is necessary to use sizes between those specified by a commonly used gage, other gages must be resorted to, in order to specify the desired dimensions.

The following extract from a letter received from a representative of one of the large machinery manufacturing concerns describes the situation clearly:

I am chief draftsman at one plant of a company which operates four drafting departments. Each department specifies different gages for the same material. I find coil springs specified under four gages, and the same confusing conditions prevail with sheet metal, copper and brass. Sheet copper is specified by ounces and by the Stubs wire gage. Inasmuch as the various existing plants of our company exchange details and specifications, you can understand how confusing our drawing files are because of these conditions.

The need for a commonly accepted standard of wire and sheet-metal gages becomes more and more imperative as the manufacturing industries of the United States grow in importance and diversity. The American Society of Mechanical Engineers has appointed a committee to investigate the present systems of gages with the view of securing the adoption of some standard gage embracing the best features of all, which will be known as the standard wire and gage system recommended by the society.

The gage system, that is the system of referring to wire and sheet-metal diameters and thicknesses by numbers, is probably too firmly established to be changed. Nevertheless, it seems that we could profitably abolish the gage system in favor of a decimal system giving in every case the thickness in thousandths of an inch, instead of referring to it by an arbitrary number liable to be confused with the numbers of other gages.

* * *

The use of aluminum is constantly being extended into new fields. One of the latest applications of this metal, says the *Scientific American*, is for making foil to take the place of tin foil in wrapping up food products. Aluminum foil can now be made with a thickness of less than 0.002 inch. Aluminum powder is also coming into common use as the basis for a paint which is especially valuable for exposed metallic surfaces. Aluminum powder is very soft and adhesive, somewhat similar to graphite.

STEELS FOR TAPS, DRILLS AND MILLING CUTTERS

While any good high-carbon or high-speed steel can be used successfully for drills and milling cutters, when the requirement is simply that the steel shall possess good cutting qualities, the conditions met with in tap making make it necessary to select the steel to be used with great care. The best steel for taps must, in the first place, possess the same good qualities, as regards cutting properties and strength, as steel for other cutting tools, but, in addition, it must be so uniform in its composition that it is possible to cut the thread and harden the tap with the assurance that the lead of the thread of the hardened tool will be within certain specified limits. There are certain steels which, as far as strength and cutting qualities are concerned, would be excellent to use for taps, were it not for the fact that it is impossible to control the lead of the thread in the hardening process. Some of these steels will sometimes lengthen and sometimes become shorter in the lead, so as to make it impossible to compensate for the change in hardening by cutting the tap either long or short in the lead before hardening.

The Winter Bros. Co., of Wrentham, Mass., has experimented extensively to determine the best grade of steel to be used for high-class taps—that is, taps that after hardening will be as true to size, both as regards diameter and lead, as possible. During the last two years this firm has tried out twenty-six different kinds of steel and has finally settled upon using a steel made by an English maker, because this steel was found to be more uniform than any steel obtainable elsewhere. The results of the Winter Bros. Co.'s experiments are, in a general way, as follows:

The best steel to use for tapping cast iron and brass is one containing from two to three per cent tungsten, but otherwise having the same composition as an ordinary high-carbon steel, that is, with from about 1.15 to 1.25 per cent of carbon. This steel, if uniform in its composition, will contract or shorten 0.002 inch per inch in hardening, the same as most carbon steels. When hardening, it should be heated to a higher heat than a regular carbon steel, possibly to a temperature of 100 degrees F. higher (or up to about 1525 degrees F.) than that used for a carbon steel. It will also stand a greater variation in its hardening heat, and is, hence, easier to handle than steels that require closer watching in this respect.

The best steel for taps to be used on steel, as far as strength is concerned, is vanadium alloy steel containing from 0.25 up to 1 per cent of vanadium. The greater the vanadium content, the greater is the strength of the steel. The objection to this kind of steel for taps, however, is that it is very uncertain as regards its change in hardening. It is likely either to shorten or lengthen up to 0.002 inch per inch, and, hence, it is practically impossible to secure taps of correct lead when using this steel. The carbon content is the same as in regular carbon steels used for this purpose—from 1.15 to 1.25 per cent. An advantage of the steel is that it is easily hardened as it will stand a variation in the hardening heat of about 100 degrees F. without showing any marked difference in the qualities of the hardened tap.

It should be mentioned, however, that while the vanadium alloy steel experimented with by the Winter Bros. Co., proved very uncertain as regards its change in hardening, it is possible that the vanadium had no influence in this matter. It may be that the mere addition of vanadium to a steel which without vanadium will change uniformly, would not injure it in this respect. This, however, is a matter that has not been decided, and further experiments would prove of value.

Expensive special steels are obtainable in the market that will show practically no change whatever in either the lead or diameter of a tap when hardened, but steels of this character, while excellent in special instances, are not commercially suitable for tap making on account of the increased cost. Hence, in order to meet the requirements of the trade, the tap maker is forced to look around for a steel, the price of which is not prohibitive and which, at the same time, will meet the requirements as regards strength and uniformity.

These conditions are fairly well met in certain English and Swedish steels. These steels are more uniform as regards the change in hardening than are ordinary American tool steels, and they also differ from most of these steels in one particular: they nearly always lengthen, instead of shortening, about 0.002 inch per inch in hardening. The objections to English and Swedish steels are that the bars are not rolled as well as are those of American manufacture; they are rougher, they are not always round, and sometimes they are larger in diameter at one end of the bar than at the other.

High-speed steel is not used to any great extent for taps, one reason being the difficulty of hardening a high-speed steel tap with its fine cutting edges, which cannot be ground after hardening and which are liable to be injured by the extreme heat to which high-speed steel must be subjected in the hardening process. A high-speed steel suitable for taps should contain from 0.60 to 0.75 per cent of carbon and from 15 to 20 per cent of tungsten. This steel will harden at from 2100 to 2200 degrees F. The temper should be drawn at from 500 (in some cases) to 1000 degrees F. High-speed steel taps have been found especially advantageous for automatic screw machine work, particularly when tapping in brass or bronze. When used under these conditions, it has been found that the production per tap has been increased from five to fifteen times by the use of this material for the taps. The price of taps made from high-speed steel is, on an average, from three to four times that of ordinary carbon steel taps. The strength of high-speed steel drill rod, when properly hardened and tempered, is, on an average, slightly greater than that of carbon steel drill rod.

While, as mentioned, high-speed steel is not used to any great extent for taps at the present time, the Winter Bros. Co. states that the demand is increasing to a considerable extent. Although many tap manufacturers have had difficulty in hardening high-speed steel taps, this company has had no trouble in this respect, on account of the methods used for the purpose. A difficulty that has been met with, however, is that of keeping the cutting edges on the tools with which the high-speed tool taps and dies are threaded. The tools wear so fast that it is very difficult to cut smooth threads of correct form.

The superiority of the English and Swedish steel over the American made steel is very difficult to explain, because if a chemical analysis is made, it is often found that the American steel is freer from impurities—phosphorus and sulphur—than are these foreign steels; yet the latter will have greater strength, possess as good cutting qualities, and show greater uniformity after hardening. The cause, no doubt, is to be found in the different composition of the iron ores and the different processes to which American and foreign steels are subjected while being manufactured into tool steel.

While high-speed steel is not used to a great extent for taps, it is being used to a constantly increasing extent for milling cutters and drills. It is always advisable to use high-speed steel for these tools if they are used in regular manufacturing work. A high-speed steel cutter, for example, can be run at a cutting speed of from 100 to 125 feet per minute, while a carbon cutter should not be run at a higher speed than from 50 to 60 feet per minute. The high-speed steel cutter will also last from three to four times as long between grindings as a carbon steel cutter. Hence, it is safe to say that the output of the high-speed steel cutter between grindings will be from six to eight times that of a carbon steel cutter, while the price of high-speed steel milling cutters is only about three times that of carbon steel cutters.

Practically any good brand of carbon steel or high-speed steel is satisfactory for milling cutters or drills. Vanadium increases the strength and is, therefore, of special value in steel used for drills. High-speed steel drills have a capacity of from five to six times (in some cases up to ten times) that of carbon steel drills. For the larger sizes of drills, in manufacturing work, high-speed steel is of a decided advantage, as the price for drills larger than 5/8 inch in diameter is only about three times that of carbon steel drills. On the smaller sizes, however, the price of the high-speed steel drills increases proportionately to that of carbon steel drills, so that for a 1/8-inch drill the price is about seven times greater when using high-speed steel than when using carbon steel. Hence, the advantage in using high-speed steel for small sizes of drills is not as great, and, in some cases, the use of high-speed steel on the smaller sizes may be inadvisable.

While, as a general rule, it is advantageous to use high-speed steel cutters for all manufacturing work, there are some exceptions. Angular cutters, having a sharp corner, cannot be run at the high speed most advantageous for high-speed steels without danger of breaking off the weak points on the teeth, and, hence, in this case, the advantages of the better steel cannot be realized. There is also danger of burning the pointed cutting edges in hardening the high-speed steel cutters. Neither is high-speed steel particularly suited for gear-cutters or cutters used for work where the surface being cut is required to be especially smooth and of good finish. The high-speed steel cutter becomes dull at least as rapidly as does the carbon steel cutter, and in this state it will not produce a better surface than would a dull carbon steel cutter, but it has the advantage that it can continue to cut with its dull cutting edge on roughing work for a much longer time. Where a good finish is required, however, a sharp edge and a moderate speed are necessary, and as the advantages of the high-speed steel are not brought out under these conditions, there is no object in making cutters for this purpose from that material. The makers of milling cutters state that at the present time from 40 to 50 per cent of all milling cutters are made from high-speed steel.

Twist drills are made from high-speed steel to even a greater extent. Most firms making twist drills state that about 50 per cent, or perhaps slightly more, of their drills are made from this steel, while in the case of one firm, 75 per cent of all the drills made are high-speed steel drills. When carbon steel is used for drills, a steel containing as much as 1.30 per cent carbon is found to give the best results. A high-speed steel containing 18 per cent tungsten and 0.25 per cent vanadium is recommended for high-speed steel drills.

To illustrate the advantage of using a high-speed steel containing a high percentage of vanadium, the following example may be cited: A 3/4-inch drill made of a high-speed steel containing 1.25 per cent vanadium and 17 per cent tungsten was run at 600 revolutions per minute and with an 8-inch feed, drilling cast iron. The drill was used almost continuously and required to be ground but once a day. In a general way, it may be stated that high-speed steel drills containing this percentage of vanadium will last twice as long between grindings as ordinary high-speed steel drills. The price of drills of this material should not be more than 10 per cent greater than that of ordinary high-speed steel drills containing no vanadium.

When using high-speed steel for drills, it is necessary to allow a greater amount of stock for grinding after hardening than when using carbon steel. This is on account of the scale that is produced on high-speed steel tools in the hardening process. Ordinarily from 0.010 to 0.015 inch is allowed for grinding on ordinary carbon steel drills, while those made from high-speed steels have an allowance of about 0.025 inch.

In the making of reamers, there is no advantage in the use of high-speed steel, except in the case of chucking reamers. A high-speed steel reamer will not retain its size any longer than a carbon-steel reamer will, and with the slow speed at which hand reamers are used, there would be no other advantage to be gained.

* * *

According to an item in *Engineering*, the Russian Government has decided upon building a railway from Vladikavkas to Tiflis, right through the Caucasus mountains. The distance between these two cities by a straight line is only 125 miles, but, at present, it can be covered by rail only by making a long loop around the Caucasus chain, a journey of 990 miles long. The new project requires, however, the construction of a tunnel nearly 16 miles long, at a height more than 4000 feet above sea level. It is estimated that eight years will be required for the construction. Another interesting tunneling project of considerable magnitude is that being planned at Montreal, Canada, where it is proposed to construct a tunnel under the St. Lawrence River for the use of all Canadian railways.

DYNAMICS OF GAS ENGINE CAMS*—1

AN INVESTIGATION INTO THE RELATIVE MERITS OF DIFFERENT TYPES OF CAMS

BY M. TERRY†

To design a cam of proper shape for a given movement requires, in the majority of cases, only a general knowledge of the elements of mechanism. However, the timing cams of a gas engine—most notably a marine, automobile or aerial engine—where the parts in motion move at a high velocity, constitute an exception. To design this class of cams of the proper shape requires a full working knowledge of mechanics, and it seems that the correct design of these cams is a subject generally neglected by most draftsmen and designers. There is a great temptation to treat the timing cams as mere trips, intended to give a certain lift to their respective valves. When, therefore, a designer recognizes the importance of dynamic analysis of timing cams, he finds himself practically alone in his attempt to solve the problem, as there is no reliable data on this subject available. The discussion that has so far been published has been superficial; a volume would be required to thoroughly cover the subject and do it justice.

It is the object of the writer, in the following, to analyze the different types of cams, and to make a comparison between the designs. While the present article deals primarily with the various timing cams of automobile engines, the author believes that the study of the dynamics connected with them will be of interest to all readers of MACHINERY, whether they are directly engaged in the automobile industry or not. A short introduction on the types of engines used in self-propelled vehicles, and a survey of the present situation, will help the layman to grasp the importance of the problem and acquaint him, in a general way, with the "whys and wherefores" of the various types of valves used on the present-day motor cars.

Need of Valves

There are two general types of gas engines, known as two- and four-stroke cycle engines; but no matter what type of engine is selected for automobile use, the cycle consists of four distinct acts, namely: suction, compression, expansion, and exhaust. In the two-stroke cycle engine these four acts are accomplished in one revolution of the crankshaft or two strokes of the piston, while in the four-stroke cycle engine these four acts are extended over a period of two revolutions of the crankshaft or four strokes of the piston.

In the two-stroke cycle engine, suitable exhaust and inlet ports are provided in the cylinder walls, which the piston in its course of travel covers and uncovers, drawing in or expelling gases, and thus acting as its own valve. (See Fig. 1.) The piston of a four-stroke cycle engine, however, cannot unassisted be its own valve, as it will uncover both ports every other stroke, while the four-cycle action requires the opening of the ports only once in four strokes of the piston. Hence the need of auxiliary valves.

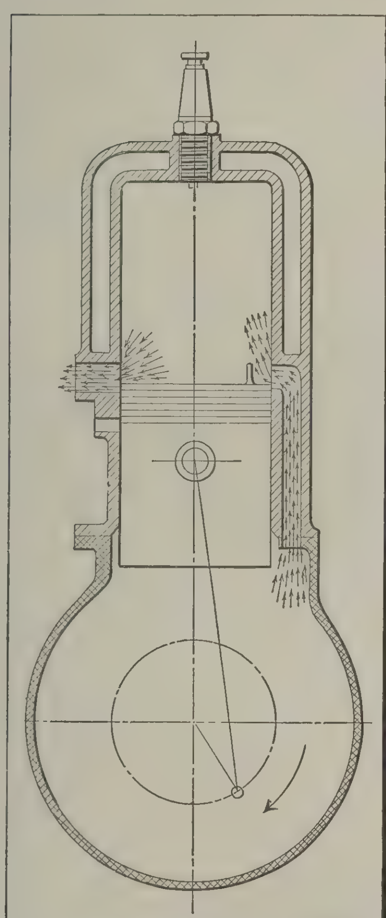

Fig. 1. Section through Three-port, Two-stroke Cycle Engine

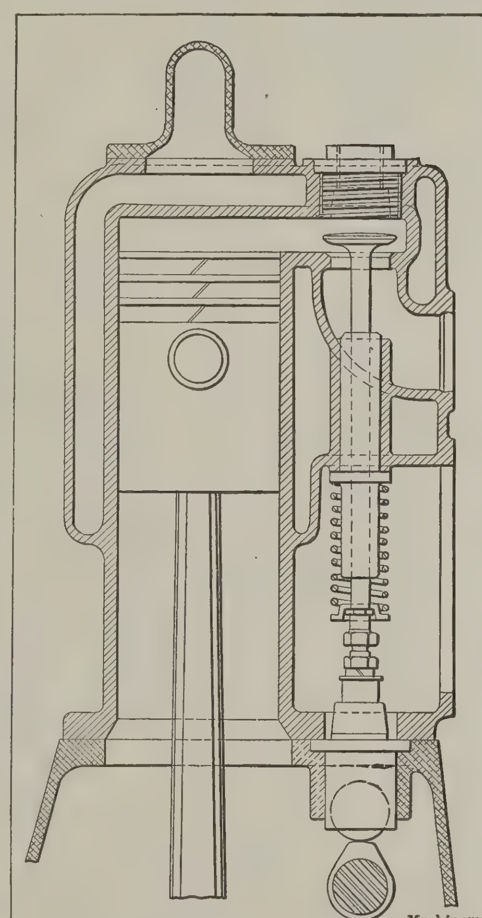

Fig. 2. Section through Poppet Valve Engine of the L-type

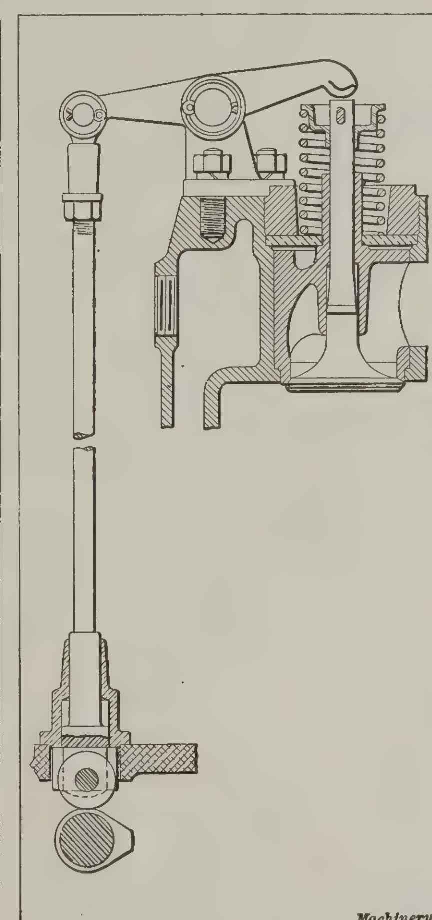

Fig. 3. Section through Valve of a Poppet Valve Engine of the Overhead Type

Types of Valves

The great majority of automobile engines operate on the four-cycle principle. These engines can be classified in various ways—horizontal or vertical, long- or short-stroke, water- or air-cooled, etc.; but, the classification which interests us most at present is that based on the type of valves employed. When studied from this point of view, any engine can be placed in one of the three following groups:

1. Poppet valve engine, shown in Figs. 2 and 3.
2. Sliding piston-valve engine, shown in Fig. 4.
3. Rotary valve engine, shown in Fig. 5.

At present the first group is by far the largest, and the poppet valve engines represent a well tried out, established and conventional form of design. The second group, up to a

* See MACHINERY, engineering edition, February, 1911, "Timing an Offset Automobile Engine," and other articles there referred to.
† Address: 910 E. Washington St., Ann Arbor, Mich.

short time ago, was in its experimental stage, but with the recent advent of the "Silent-Knight" engine, it is considered by some to be the coming rival of the first group. The rotary valve engines are conceded to be in a purely experimental stage of development.

In the last group the inlet and exhaust valves have a continuous rotary motion, accomplished either by direct gearing with the crankshaft, or by means of an endless silent chain driven by the crankshaft. Thus, on account of the continuous

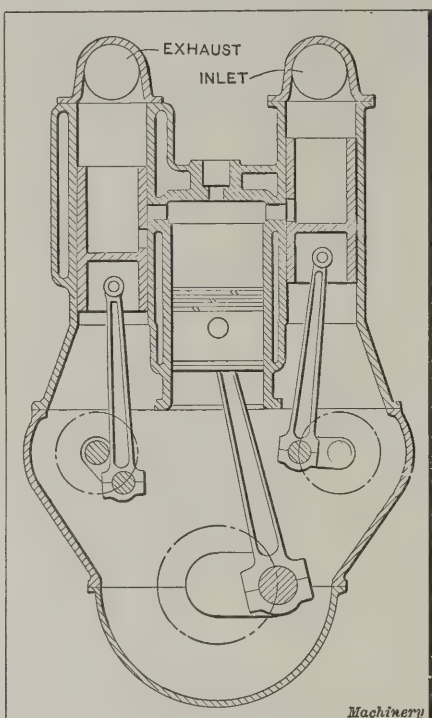

Fig. 4. Sliding Piston-valve Engine

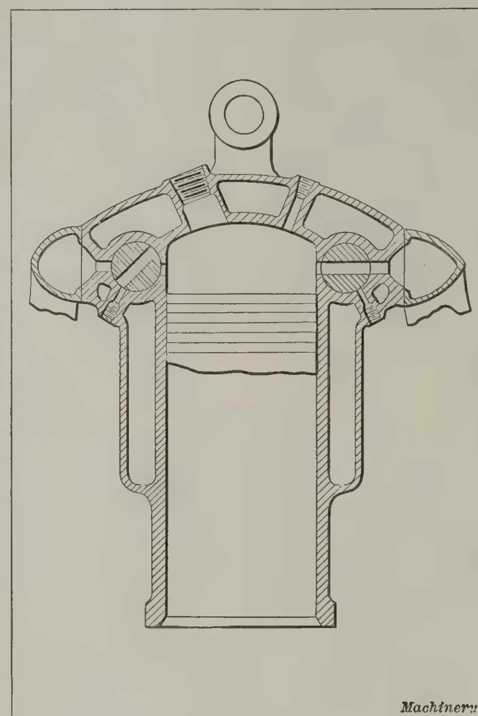

Fig. 5. Arrangement of a Rotary Valve Engine

rotary motion of the valves, the cam problem does not exist in this group.

The first two groups have the feature of reciprocating valve motion in common. The valve mechanism of the sliding sleeve engine is a miniature reproduction of the main working parts of the engine; in other words, it consists of a secondary crankshaft, connecting-rods and pistons (or sleeves as used in the "Silent-Knight" engine). The secondary crankshaft receives its motion from the main crankshaft, either by means of gears or an endless silent chain, and with the assistance of the small connecting-rods it imparts a reciprocating motion to the secondary pistons—valves or sleeve-valves, as the case may be. These valves travel in a smooth bore with no obstacles in their paths. The highest and the lowest points of their travel are determined by the throw of the secondary crankshaft. In other words, the entire linkage of the sliding piston or sleeve-valve is rigid.

As mentioned before, the poppet valves also have a reciprocating motion, but, in order to insure gas-tightness in the working cylinder, the valves must be brought tightly against their seats (flat or conical) which are formed either in the main casting or in inserted cages at right angles to the path of the valves. (See Figs. 2 and 3.) In a properly working gas engine these seats determine, then, one of the extreme points in the line of valve travel, and with this arrangement, the use of rigid linkage for poppet valve gears is out of the question. Even if it were possible by accurate machining or careful adjustment to introduce some kind of rigid linkage, the difference in contraction and expansion of the cylinder casting and the valve stems would soon result in an appreciable gap between the valves and their seats, which, in turn, would be the cause of gas leakage, poor compression, pre-ignition, back-firing and other well-known gas engine troubles; hence, the apparent necessity for a linkage with one or more "broken joints," a cam to open the valve, and a spring to close it.

It is an admitted fact that by far the greater portion of the noise caused by the modern automobile engine is due to its valves. As the noise is due directly to the pounding action of the valve gear at its broken joints and at the valve seat, no improvement along this line can be expected until designers turn their attention to the study of the various cam shapes and their respective dynamic effects.

Brief History of Development of Automobile Engine Cams

The design and construction of power plants of the early motor cars were based largely on two elements: guesswork and the then established practice in stationary and marine gas engine work. In the latter class of engines a cam of the type shown in Fig. 6 was used almost exclusively, so there is but little wonder that it was also adopted by the early automobile manufacturers. This cam is still retained in automobile engines when a so-called "mushroom" type of follower is employed; but for a roller-follower it was displaced entirely by the so-called "tangential" cam.

Some eight years ago the Buick Motor Co., then located in Detroit, Mich., and engaged in the construction of marine engines, was experimenting with its first model of self-propelled

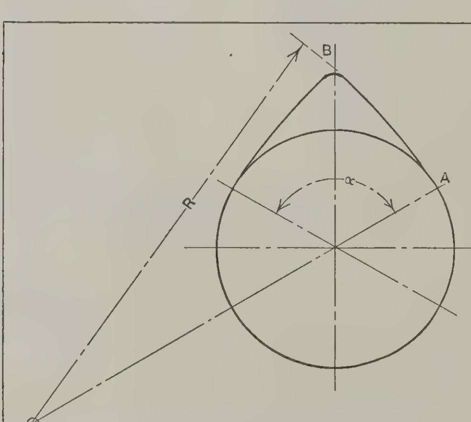

Fig. 6. Cam used on Early Automobile Engines

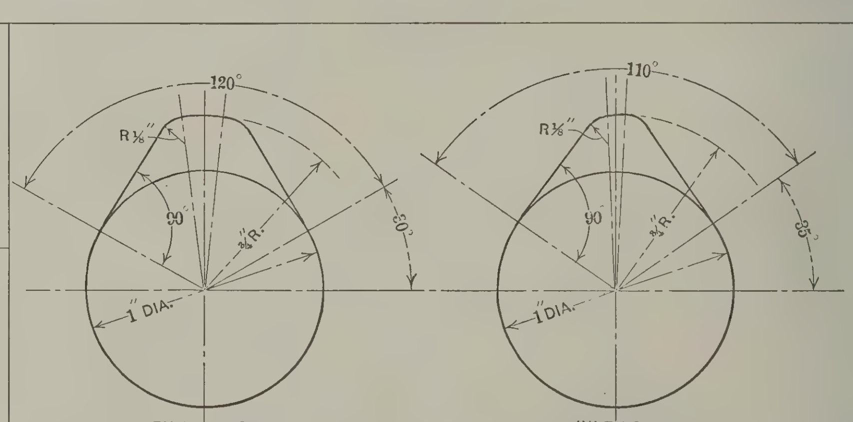

Fig. 7. Dimensions of Exhaust and Inlet Cams

vehicles. It was not long before it was discovered that the old marine type of cam was altogether too noisy on high engine speeds. In searching for a more suitable shape of cam, it was observed that the noise seemed to decrease as the radius of the arc *AB*, Fig. 6, was increased. In the light of this discovery, the next idea that naturally suggested itself was to make the radius of the arc infinite, or, in other words, to make the arc *AB* a straight line. The results obtained were so gratifying that this new cam—now known as tangential—was immediately adopted, and the Buick Motor Co. was soon

followed in this by other manufacturers. At present, the vast majority of the motor car engines are equipped with tangential cams.

Whether the Buick Motor Co. deserves the entire credit for the introduction of the tangential type of cam or not, is, of course, pretty difficult to say. There is no doubt, however, that the tangential cam is merely a product of experimental development, whereas the uniformly accelerated and retarded motion cam is a product of study based on the well-known laws of falling bodies. The fact that the simple contour of the tangential cam makes it an easy manufacturing proposition and permits of ready detection of error in the inspection room, undoubtedly hastened its general adoption in the motor car field; but the very simplicity of its shape has aroused suspicion in the minds of many as to its other advantages, and has been the cause of many proposals to have it replaced by the uniformly accelerated and retarded motion cam. Perhaps one of the earliest proposals made in this country was

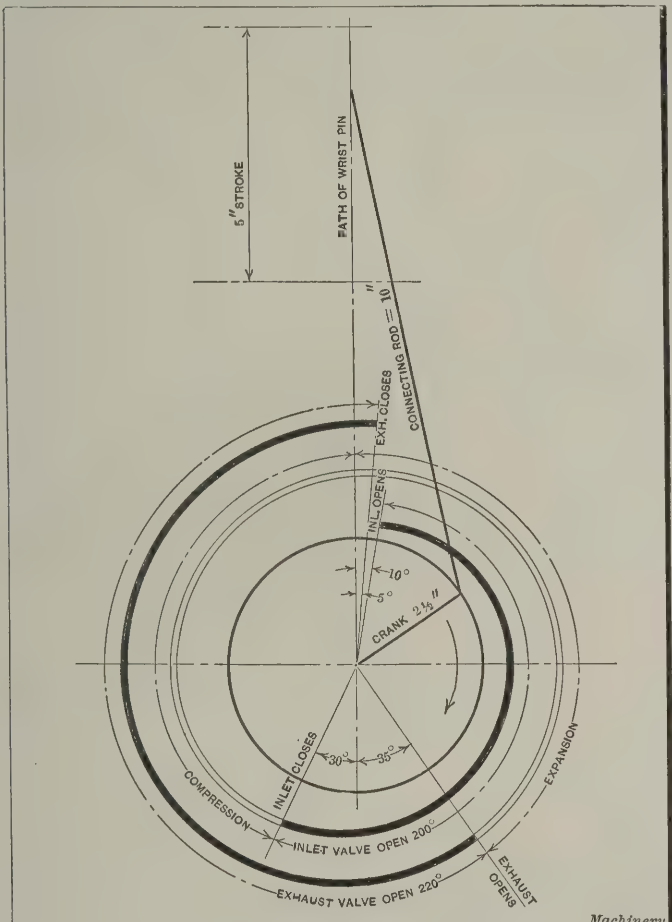

Fig. 8. Timing Diagram for Cams

published in 1905 by Mr. P. M. Heldt, editor of the *Horseless Age*. This question was again referred to in that publication in 1911 (issue of June 28, page 1083), which indicates that an opposite view—if one were ever held by anybody—was never given any publicity, or, at least, not sufficiently proved.

The author wishes to state at the outset that until a short time ago he shared Mr. Heldt's opinion, and that he was greatly puzzled by the results of a practical experiment which turned out contrary to his expectations. When he started the present investigation it was his purpose to prove the superiority of the uniformly accelerated and retarded motion cam over its tangential rival, but his logic brought him to entirely different conclusions.

Analysis of Tangential Cam

Let us now first take an actual case from practice and analyze the working conditions. Suppose an engine of 4-inch bore and 5-inch stroke is to have the following timing and general dimensions:

Exhaust opens 35 degrees ahead of the lower dead center.
Exhaust closes 5 degrees past the upper dead center.
Inlet opens 10 degrees past the upper dead center.
Inlet closes 30 degrees past the lower dead center.
Cam to be of the tangential type.
Base circle of the cam = 1.000 inch diameter.
Cam roller circle = 1.000 inch diameter.
Lift of cams = ¼ inch.
Radius of cam fillet = ⅛ inch.
Clearance angle = 5 degrees.
Maximum speed of the engine at which quiet operation of valves is expected, to be between 1600 and 1700 R. P. M.

In regard to timing, the reader is referred to the article, "Timing an Offset Automobile Engine," in MACHINERY, engineering edition, February, 1911. The problem of clearance and clearance angle will be taken up in detail later on.

Fig. 8, known as a timing diagram, represents the path of the piston, length of connecting-rod, length of crank, and the crank circle. The opening and closing points of the valves are referred to the latter. Thus the inlet valve of the first cylinder begins to open at the instant the first crank pin is 10 degrees past the upper dead center, etc.

It is evident then from Fig. 8 that the exhaust valves are open during 220 degrees and the inlet valves during 200 degrees of the crankshaft motion. Since the camshaft revolves at one-half the speed of the crankshaft, the angles of exhaust and inlet cams will be 110 degrees and 100 degrees, respectively. To these angles we must add 10 degrees (twice the clearance angle), giving 120 degrees for the exhaust and 110 degrees for the inlet cam. This is shown in Fig. 7. The dimensions given are those found on a manufacturing drawing. Assuming that the steel cams in their finished forms correspond exactly to the dimensions given in Fig. 7, we shall proceed to analyze their action.

From Fig. 2 it is clear that the motion of the valve gear as a whole is identical with the motion of the cam roller center. The motion of either is referred to the camshaft center, which is regarded as stationary. The camshaft turns in a left-hand direction with a constant angular speed, and the roller center (as well as the rest of the valve gear) moves up and down in a straight line with a variable speed. The relative motion of the cam and roller centers will remain unchanged if we consider the cam stationary and the roller following the contour of the cam.

Exhaust Cam

In Fig. 9 is shown the exhaust cam and its roller. The face of the cam (CC_4) is a straight line, and, as the roller moves along this line, its center A describes a straight line parallel to CC_4. As the roller center assumes its successive positions at A_1, A_2, A_3, etc., its distance from the cam center increases.

If D is the distance of A from O, in inches, corresponding to any angle θ, then:

$$D = \frac{OA}{\cos\theta} = \frac{OC + CA}{\cos\theta} = \frac{\frac{1}{2} + \frac{1}{2}}{\cos\theta} = \frac{1}{\cos\theta}$$

Now, if the roller did not rise at all, its center A would have followed the circular path AB, the center of which lies at O. Consequently, the actual rise of the roller corresponding to θ_1, θ_2, etc., is measured by A_1B_1, A_2B_2, etc.

If L stands for the lift or rise of the roller center in inches, then

$$L = D - OA = \left(\frac{1}{\cos\theta} - 1\right)$$

This equation represents the law governing the motion of the valve gear as long as the roller is in contact with the face of the cam, *i. e.*, from C to C_4. As this law is expressed in terms of θ it is of importance to us to know the limiting values of θ between which it operates.

From Fig. 9 it is clear that the limiting values are zero and the angle AOA_4. The problem is to find the value AOA_4 in degrees. For the sake of clearness, we shall use the right half of the cam; the latter being symmetrical, the same construction would apply to either side. CC_4 is tangent at C to the base circle of the cam and at C_4 to the fillet circle, the center of which lies at F. Hence CC_4 is at right angles to OA at C and to FC_4 at C_4. Draw EF parallel to CC_4. Then EF is at right angles to OA. Also, since A_4C_4 is at right angles to CC_4 at C_4, line FC_4A_4 is a straight line.

By construction,

$$EC = FC_4 = FC_7 = \tfrac{1}{8} \text{ inch.}$$
$$OE = OC - CE = \tfrac{1}{2} - \tfrac{1}{8} = \tfrac{3}{8} \text{ inch.}$$
$$OF = OC_7 - FC_7 = \tfrac{3}{4} - \tfrac{1}{8} = \tfrac{5}{8} \text{ inch.}$$

$$EF = \sqrt{\overline{OF}^2 - \overline{OE}^2} = \sqrt{\tfrac{25}{64} - \tfrac{9}{64}} = \tfrac{1}{2} \text{ inch.}$$

$$EF = CC_4 = AA_4 = \tfrac{1}{2} \text{ inch.}$$

Hence, $\tan AOA_4 = \dfrac{AA_4}{OA} = \dfrac{\frac{1}{2}}{1} = \dfrac{1}{2}$, and angle $AOA_4 = 26$ deg. 34 min.

The first law of motion of our valve gear, as we shall refer to it from now on, is expressed by the equation:

$$L = \frac{1}{\cos\theta} - 1$$

the limiting values of θ being 0 and 26 degrees 34 minutes. Now, let us look into the motion of the valve gear while the roller is traveling on the cam fillet. In order to make our discussion clearer, we shall carry out the geometrical construction simultaneously in Figs. 9 and 10. It is evident from Fig. 9 that, as the periphery of the roller moves along the fillet arc C_4C_7, the center of the roller describes the arc A_4A_7 concentric with C_4C_7. In other words, the roller center moves in an arc of a circle the center of which lies at F and the radius of which is FA_4.

Now, $FA_4 = FC_4 + C_4A_4 = \frac{1}{8} + \frac{1}{2} = \frac{5}{8}$ inch, and $OF = \frac{5}{8}$ inch. Then, if in Fig. 10, with F as a center, we describe a circle of radius FA_4, the circumference of the circle will pass through O. Note, however, that this is not always the case. In this instance it is due to the fact that the roller diameter is equal to the diameter of the base circle of the cam, and also to the fact that the radius of the fillet is made equal to one-half of the cam lift. The roller center, as explained before, describes the arc A_4A_7. Take any position of the roller center, as A_5; its distance from $O = OA_5 = OA_7 \cos\beta_5 = 1.25 \cos\beta_5$ inch.

With O as a center and OA as a radius, strike the arc AB (same as in Fig. 9). The actual lift of the roller center at A_5 equals:

$$B_5A_5 = OA_7 \cos\beta_5 - OB_5 = 1.25 \cos\beta_5 - 1.$$

Since A_5 is any position of the roller center on its path A_4A_7, the same equation will apply to every point on that path. Hence,

$$L = 1.25 \cos\beta - 1.$$

This equation represents what we shall term the second law of the valve gear motion.

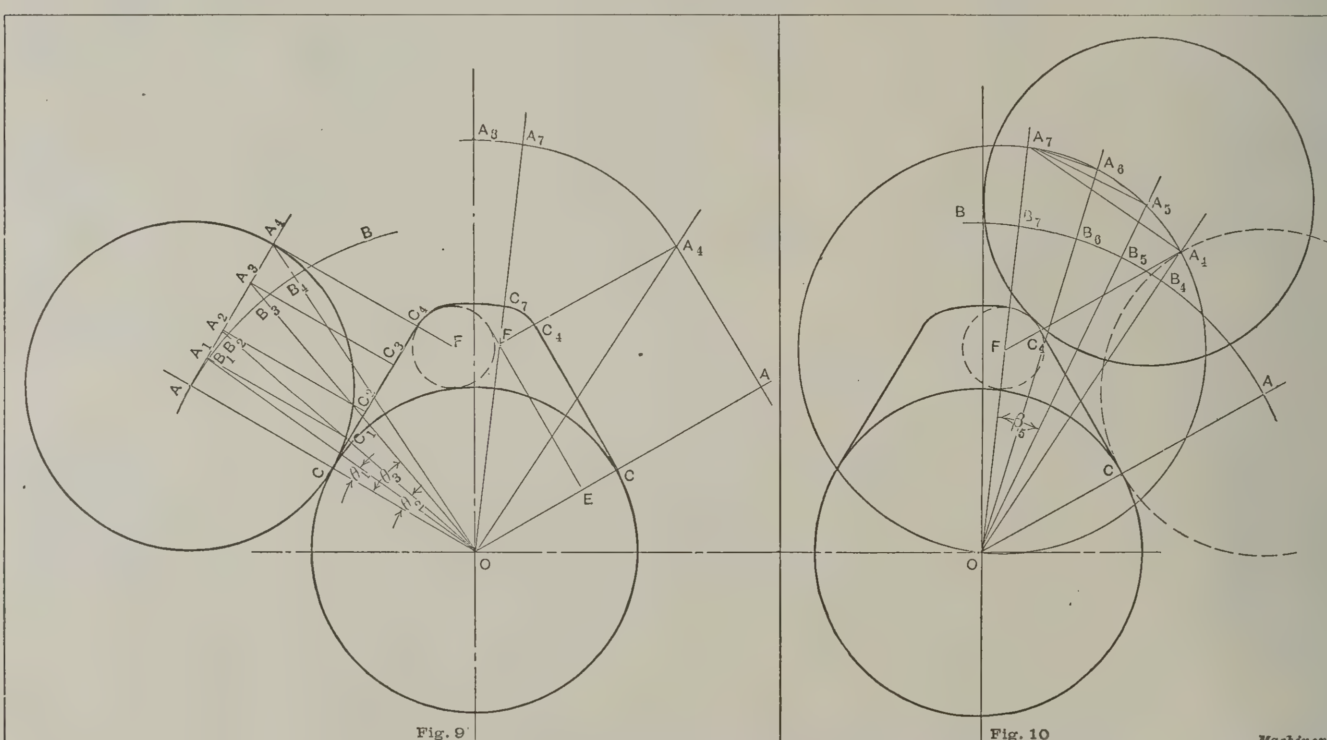
It will be observed that this second law of motion is expressed in terms of a constantly decreasing angle. The lift increases as the angle β decreases. The limits of β are 0 degree and the value of angle A_4OA_7. It remains to determine the value of this angle.

Angle $AOA_4 = FA_4O = A_4OA_7$. But angle $AOA_4 = 26$ degrees 34 minutes. Hence angle $A_4OA_7 = 26$ degrees 34 minutes.

The valve, then, attains its full lift of ¼ inch in 53 degrees 8 minutes of the angular rotation of the cam. During the remaining portion of cam's rotation, known as dwell—equal to 6 degrees 52 minutes, considering only one-half of the cam—the valve remains stationary, and its third law of motion may be expressed as $L = \frac{1}{4}$ inch.

Inlet Cam

Thus far we have considered the exhaust cam only, but it can be easily demonstrated that the motion of the inlet valve gear is identical with that of the exhaust, except that it begins and ends 5 degrees later with respect to the horizontal center line of the camshaft. By comparing Fig. 11 with Figs. 9 and 10, the reader will have no trouble in discovering the truth of this statement for himself. The laws of motion and the limits between which they operate are the same for both the inlet and exhaust valves, and this fact can be taken advantage of in making the valve springs interchangeable, as well as the rest of the valve gear. It may be stated here, in a general way, that, while the roller moves along the face of the cam, the valve has an accelerated motion, and during the roller's contact with the cam fillet, the valve has a retarded motion. In fact, the sole object of the fillet is to serve as a cushion.



Figs. 9 and 10. Diagrams used for the Analysis of the Dynamics of a Tangential Exhaust Cam

There are several camshafts made with the exhaust cam fillet of somewhat greater radius than that of the inlet cam, in the belief that the exhaust cam requires more cushioning. That there is absolutely no reason for it may be demonstrated by the study and comparison of Figs. 9, 10 and 11.

Lift, Velocity and Acceleration

Let

- α = the angle formed at any instant during the upward motion of the valve by the line of cam and roller centers with the line OA. The maximum value of α is 53 degrees 8 minutes, according to Figs. 9, 10 and 11. For the sake of simplicity, we will make it 53 degrees. (Tables I and II, column 1.)
- θ = the angle that enters in the equation of the first law of motion. It is identical with α except that its maximum value equals 26 degrees 30 minutes (one-half of the maximum value of α). (Table I, column 2.)
- β = the angle that enters in the equation of the second law of motion. Like α and θ it represents the angular position of the cam, but is measured from the line

OA_7. In other words, during the required motion of the valve gear, angle β decreases as α increases; the relation between β and α is expressed by the following equation: $\beta = 53$ degrees — α (Table II, column 2).

L = lift of valve gear in inches corresponding to any angle α. The values of L are computed from the equations representing the first two laws of motion (Tables I and II, column 4).

v = the velocity of the valve gear in inches per degree of the angular motion of the cam. By definition, velocity is the time-rate of change of position, and since our time unit is that corresponding to an angular movement of one degree, the numerical difference between any two successive values of L will represent the average velocity during that interval of time. (Tables I and II, column 5.)

a = acceleration in inches per degree per degree of the angular motion of the cam. By definition, acceleration is the time-rate of change of velocity, and, again, since our time unit is one degree, the numerical difference between any two successive values of v is the average acceleration during that interval of time. (Tables I and II, column 7.)

V = velocity of valves in feet per second corresponding to any value of v. (Tables I and II, column 6.)

A = acceleration in feet per second per second corresponding to any value of a. (Tables I and II, column 8.)

The last two quantities, V and A, are both expressed in gravitational units and are of great importance in our investigation. V and A can be computed from v and a respectively, but in order to do so it is necessary to establish the numerical relation between the time unit measured in seconds and the time unit as expressed in degrees.

From our specifications, the maximum speed of the engine equals from 1600 to 1700 R. P. M.; assume it to equal 1680 R. P. M. Since the camshaft revolves at one-half the speed of the engine shaft, its speed is equal to 840 R. P. M., or 14 revolutions per second. Since one revolution equals 360 degrees, the camshaft turns through $360 \times 14 = 5040$ degrees in one second. Therefore, the time unit corresponding to one degree is 1/5040 second. For the sake of simplicity we shall assume one degree = 1/5000 second, or one second = 5000 degrees. Hence,

$$V = \frac{5000\,v}{12} \quad \text{(Tables I and II, column 6.)}$$

$$A = \frac{5000 \times 5000 \times a}{12} = \frac{25{,}000{,}000\,a}{12}$$

(Tables I and II, column 8.)

It may occur to some that in carrying out the values of L, column 4, Tables I and II, to seven decimal places one loses "the sense of values," and that in practice both the cam and the roller will vary enough to affect the third decimal place by one or two units. Indeed, were we to attach importance to any one value of L, it would be folly to carry it out beyond the third decimal place, but what we aim to determine is not the individual values of L, but the succession of these values. This method gives us four significant places for the values of a (column 7) which is not too much. If the cam and its follower were a few thousandths of an inch below or above their standard dimensions, the relative differences would be the same throughout columns 3 and 4 of both tables. The values of a would all be changed, but these new values would differ from one another in the same manner as those given in Tables I and II.

It must be borne in mind that the method pursued for finding v and a is an approximate one. The exact values of v and a at any instant can be obtained only by differential calculus. However, since the values of L were taken close together (one degree apart) this method gives as accurate results as are required for our purpose.

Tables I and II cover only the upward motion of the valve, but a little thought will show that the same values of

v and a and of V and A taken in reverse order will apply to the downward motion as well, with a changed sign of acceleration. The tables for the inlet cam will be precisely the same. The tables as well as the acceleration curve plotted from them (see Fig. 12) show that

the cam starts the valve gear on its upward journey with an ever-increasing acceleration. Readers familiar with mechanics know that even were the acceleration constant, the cam and its follower would be in contact under pressure, for a constant acceleration of the follower can be due only to a constant force acting on it, *i. e.*, a constant pressure of the cam on the follower. Since, in our case, the acceleration is of a gradually increasing nature, it is more than sufficient to keep the cam in contact with its follower, and consequently the pressure of the spring is unnecessary as long as the roller moves along the face of the cam.

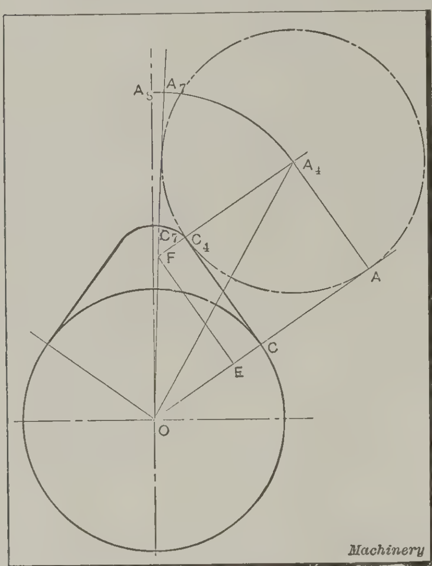

Fig. 11. Analysis of Tangential Inlet Cam

At $a = 26$ degrees 30 minutes (point B in acceleration diagram, Fig. 12), the state of things changes. Acceleration vanishes instantly, but by this time the valve gear has acquired a definite velocity. Owing to this velocity it possesses a certain amount of energy which is consumed in compressing the valve spring through a certain distance. The spring absorbs this energy at the expense of the now decreasing velocity of the valve. A decreasing velocity can be due only to a negative acceleration; in other words, the spring does all the work of retardation (neglecting slight friction and force of gravity). It can do it in a number of different ways, but the best way is plainly the one that will insure contact (under slight pressure) of the cam with its follower, and, in order to do that, the spring must exert pressure sufficient to produce accelerations somewhat greater than those shown in Column 8, Table II, and represented in Fig. 12 by the portion BC of the curve.

The first part of the downward motion of the valve is due entirely to the pressure of the spring. The motion is symmetrical with that of the last part of the upward motion and a spring designed for this will be satisfactory for both motions. At D, Fig. 12, the acceleration changes sign and becomes negative—this time the cam doing all the work of retardation. If the spring pressure is to vanish instantly at this point, the cam will retard the valve just as effectively.

Valve Springs

There remains now only the problem of designing a suitable valve spring. Let,

T = pressure of the spring in pounds at any point between B and C, Fig. 12.

A = acceleration (in feet per second per second) necessary at that point to keep the cam in contact with its follower.

m = mass of the reciprocating parts of the valve gear, including one-half the mass of the spring itself.

Then, $T = m \times A$.

Assuming the weight w of the reciprocating parts to be 1.6 pound,

$$m = \frac{w}{g} = \frac{1.6}{32} = \frac{1}{20}$$

$$T = A \times \frac{1}{20} = \frac{A}{20}$$

The valve springs most commonly used on automobile engines are of the type shown in Figs. 2 and 3. Any helical spring develops pressure in direct proportion to the amount of distortion it undergoes, provided its elastic limit is not exceeded. It will, therefore, prove useful to plot a curve BC, Fig. 14, using lifts for abscissas and spring pressures for ordinates. This can be easily accomplished by selecting, from Table II, eight or ten values of L and the corresponding values of A. Table III is made up of these values selected at random; the third column of this table gives the spring pressures in pounds. In Fig. 14, the curve BC corresponds to curve BC in Fig. 12.

The compression curves of the springs shown in Figs. 2 and 3 are straight inclined lines (within the elastic limit), and in accordance with our preceding discussion the compression curve of our spring must be slightly above BC, if the cam and its follower are to be kept in contact under pressure. There are two more conditions to which our spring must conform. The first of these is that the maximum safe load of the spring should not be exceeded when the valve reaches its full lift. The second condition is that, when the piston is drawing in a fresh charge, the spring pressure must be sufficient to keep the exhaust valve tight on its seat against the back pressure of the exhaust gases in the muffler.

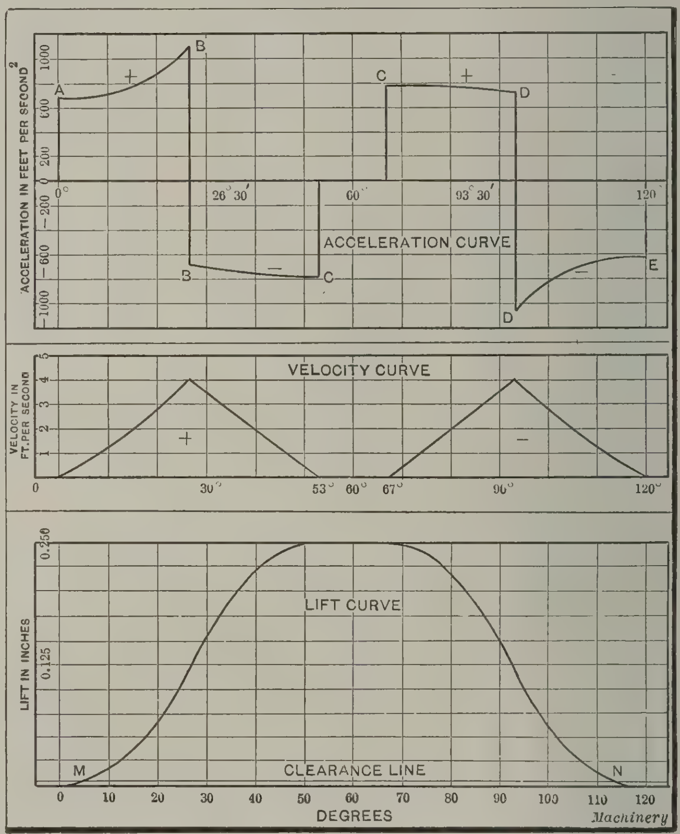

Fig. 12. Acceleration, Velocity and Lift Curves of Tangential Cam

Suppose that the valve is of the dimensions shown in Fig. 13, that the back-pressure of exhaust gases is about 8 pounds gage, or about 23 pounds absolute, and that the pressure in the cylinder on the suction stroke drops to 12 pounds absolute. Total difference in pressures on valve head is:

$$23 \times \frac{\pi}{4} \times \left[(1\tfrac{1}{4})^2 - \left(\frac{5}{16}\right)^2 \right] - 12 \times \frac{\pi}{4} \times \left(1\frac{11}{16}\right)^2 = 12$$

pounds.

When the valve is closed, *i. e.*, when $L = 0$, the spring pressure must be somewhat in excess of 12 pounds or else gas-tightness at the seat will not be secured. In practice, probably nothing short of 30 pounds would do. There are two reasons for this discrepancy between theory and prac-

tice: 1. The pressure in the exhaust header, which is located in the immediate neighborhood of the exhaust valves, must, on account of restricted passages, be somewhat higher than the back-pressure in the muffler; 2. The exhaust of burnt gases does not take place in a continuous stream, but comes in "puffs," and, thus, the pressure in the header is of a pulsating nature, with a maximum instantaneous value considerably in excess of the muffler pressure.

In designing a spiral spring, the two following formulas

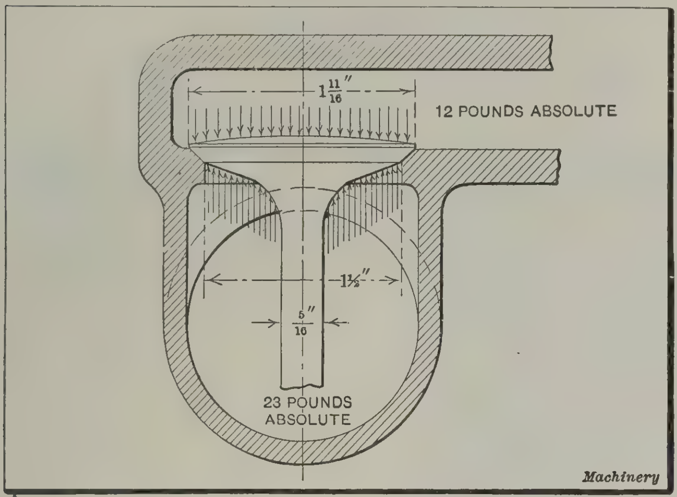

Fig. 13. Section through Exhaust Valve

given by Unwin (Part I, page 39) are generally used by designers:

$$P_1 = \frac{180{,}000\, d^4}{nr^3} \qquad (1)$$

$$P = \frac{12{,}000\, d^3}{r} \qquad (2)$$

where $P =$ maximum safe load of the spring in pounds.
$P_1 =$ pressure on spring in pounds per inch of deflection,
$n =$ number of full coils,
$d =$ diameter of wire in inches,
$r =$ mean radius of the spring.

Cut and try methods are generally applied to Formulas (1) and (2). Practical considerations, however, greatly reduce the tedious work of calculating the springs. The amount of room available for springs limits their outside diameter; in

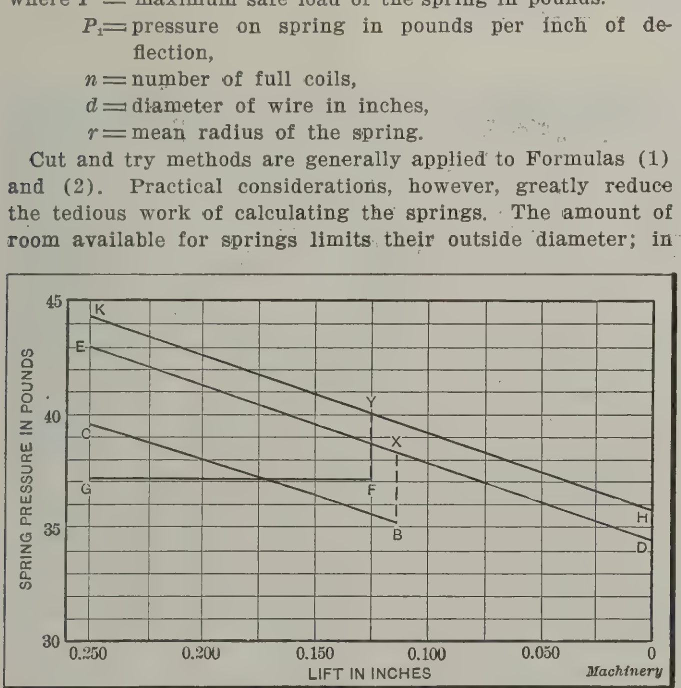

Fig. 14. Spring Pressure Diagram for Tangential and Uniformly Accelerated Motion Cams

other words, it limits r. According to Table III, the maximum pressure of the spring need not exceed 40 to 45 pounds. Making $P = 45$ pounds, and $r = \frac{1}{2}$ inch, and substituting these values in Equation (2) we get $d = 0.123$ inch.

The nearest size of wire is No. 11 B. W. G., which is equal to 0.120 inch. Therefore, making $d = 0.120$, retaining 45 for the value of P, and solving for r in Equation (2), we get $r =$ 0.462 inch.

In Equation (1) d and r are now practically determined. Referring to Table III it will be seen that the spring pressure must increase by about 4 pounds with a corresponding compression of about ⅛ inch; in other words the spring pressure per inch of deflection $= \frac{4}{1/8} = 32$ pounds.

Making $P_1 = 35$ pounds in Equation (1) and solving for n, we get $n = 10.8$ coils.

If we make the spring with eleven free coils:

$$P_1 = \frac{180{,}000 \times 0.00020736}{11 \times 0.0986} = 34.4 \text{ pounds.}$$

Now, if the spring be made 1 inch longer in its free state than when it is in place with the valve closed, its initial pressure will amount to 34.4 pounds, and with the valve at its full lift, the final pressure of the spring will amount to $34.4 \times 1.25 = 43$ pounds. The pressure line of the spring is represented graphically by line DE in Fig. 14. It will be observed that the spring thus designed fulfills all requirements. The ideal spring pressure line is the one that will practically coincide with line BC.

So far as design is concerned, our problem is now completely solved. However, if we wish to look further into the advantages and disadvantages of the tangential cam, we must compare it with some other type of cam. This method of comparison is a very useful one, for it eliminates the necessity of several assumptions, and at the same time brings out definitely both the desirable and the undesirable features of cams. A comparison with the uniformly accelerated and retarded motion cam will be made in the next installment of this article.

EDUCATION IN ACCIDENT PREVENTION

At the accident prevention meeting of the Conservation Congress at Indianapolis, October 2, Mr. Melville W. Mix, president of the Dodge Mfg. Co., Mishawaka, Ind., read a paper in which the general principles of accident prevention in his plant were outlined, and from which we have made the following extract:

"With the development of the new doctrine of indemnity in the case of occupational accidents, which disregards the assumption of risk, negligence of fellow employes or contributory negligence, as defenses to the employer, it becomes necessary to consider the question from a purely educational standpoint, establishing collaterally therewith the doctrine of prevention of accidents.

"In order to bring the matter of safety directly to the employes of the Dodge Mfg. Co., the management has prepared a plan of education and competition between departments and their foremen. This is in the form of a percentage score board, such as indicates the standing of teams in the base ball leagues. The starting point is 1000. Each division is penalized according to its accidents, minor accidents of less than one day's absence not, as yet, being considered. Each day's absence bears a percentage charge in proportion to the total number of men-days per month in each division.

"The foremen of all the divisions scoring 1000, or those holding the first three places below 1000 will receive prizes for personal interest each month. The foreman scoring the largest number of first monthly prizes for one year will receive a special prize at the end of the year. All divisions holding a percentage for the year of 1000, or the highest annual percentage, will receive two days' extra pay."

The plan is in a rather crude form at present, but it will be of daily interest because of its competitive nature, and will facilitate the inculcation of preventive measures and of individual care and forethought, as well as speedy and prompt attention to reduce the severity of the accident and shorten the time of absence. The interest in the daily score board, which is 24 feet long and erected at the main works entrance, will influence all the workers.

* * *

The council of the International Association of Chemical Societies, which met in Berlin last April, unanimously approved of Prof. Ostwald's suggestion in favor of a series of uniform sizes for chemical publications. It was recommended that all the affiliated societies adopt, for their publications, the uniform size of 16 by 22.6 centimeters (about 6 5/16 by 8 7/8 inches.). It certainly would be desirable if book publishers in general could agree on certain standard sizes for all scientific and mechanical books.

MILLING SAD IRONS

This seems to be the age of the milling machine, as it is used on work hitherto thought to be entirely out of its range. Automobile manufacturers early appreciated the possibilities of this type of machine and have achieved wonderful results from its use. It is interesting to note, however, that other manufacturers have also awakened to the possibilities of milling on certain classes of work, and have in some cases increased the output greatly. An excellent example of the application of the Becker vertical type of milling machine to the manufacture of sad iron bases was obtained in the shop of the Dover Mfg. Co., Canal Dover, Ohio.

The former method of machining these sad iron bases—removing ⅛ inch of material from the base—was to hold one base at a time in a chuck, and remove the material with a single cutting tool. A row of the machines formerly used for this purpose is shown in Fig. 1, where it will be seen that they resemble somewhat in appearance an old type lathe. Fig. 3 shows a closer view of the tool-slide and chuck in which a sad iron base is retained.

Fig. 1. "Old Lathes" formerly used for machining Sad Iron Bases

The drive is from a countershaft to the pulley A, which is held on the back-gear shaft carrying the pinion B, this gear meshing with the large gear C on the work spindle D, Fig. 1. Located on the rear end of the work spindle is another pinion E, which through the medium of an intermediate gear F, drives the back shaft G. Shaft G, through bevel gears, rotates the screw H, which imparts the traverse movement to the slide I. A pinion J, held on the front end of the screw, provides a means for rotating the latter by hand through the gear K and the handle shown.

The chuck used for holding the work is a rather antique looking affair, consisting of a plate screwed to the spindle, and recessed to receive the two jaws L and M, which are milled out to suit the shape of the casting. The work is clamped by the set-screws N and O, the screw O extending through the jaw L, while the screw N bears on a spring plunger that pinches the casting. It is only necessary to operate the set-screw N to clamp the work, when the set-screw O has once been properly set. (Note the fancy guard for the set-screw.)

These machines were arranged in a row so that one man could attend to the "gang", removing and inserting the work, keeping the cutting tools sharp, etc. Great difficulty was experienced in producing a smooth surface at the extreme ends of the sad iron base, owing to the cutting tool P springing when leaving and approaching the work. This necessitated rotating the work slowly by means of the back-gear arrangement, and using a fine feed. With five of these machines (only four are shown in Fig. 1) it was possible by keeping them going continually to turn out 1000 sad irons per day—at a rate of one casting from each machine every three minutes.

Upon the installation of the two Becker vertical milling machines shown in Fig. 2, which were equipped with rotary fixtures, this production was increased by 300 per cent (to 4000 sad iron bases per day), with a corresponding increase in the quality of the work. Instead of one man attending to five machines, each machine is attended by an operator whose attention is confined to removing and inserting the work. The milling is accomplished with a high-speed steel inserted tooth milling cutter, having fourteen blades, which support each other, obviating chatter and enabling the use of a coarse feed.

A closer view of the rotary milling fixture used is shown in Fig. 5, while Fig. 4 shows the construction of the clamping arrangement. The fixture consists of a circular base A, which is clamped, as shown, to the rotary table and is provided with cast projections forming the base of a three-point support for the sad iron base. As shown in Fig. 4, the sad iron base rests on a hardened block B, and is supported and clamped on the forward end by two hardened studs C which are beveled to grip the casting securely, when it is forced against them by the strap D. This strap is provided with a heel, and is located in a machined recess in the lug E to which the hardened block B is also fastened. The clamping strap is held against the work by a winged nut F, screwed onto a stud that is located in the cast lug.

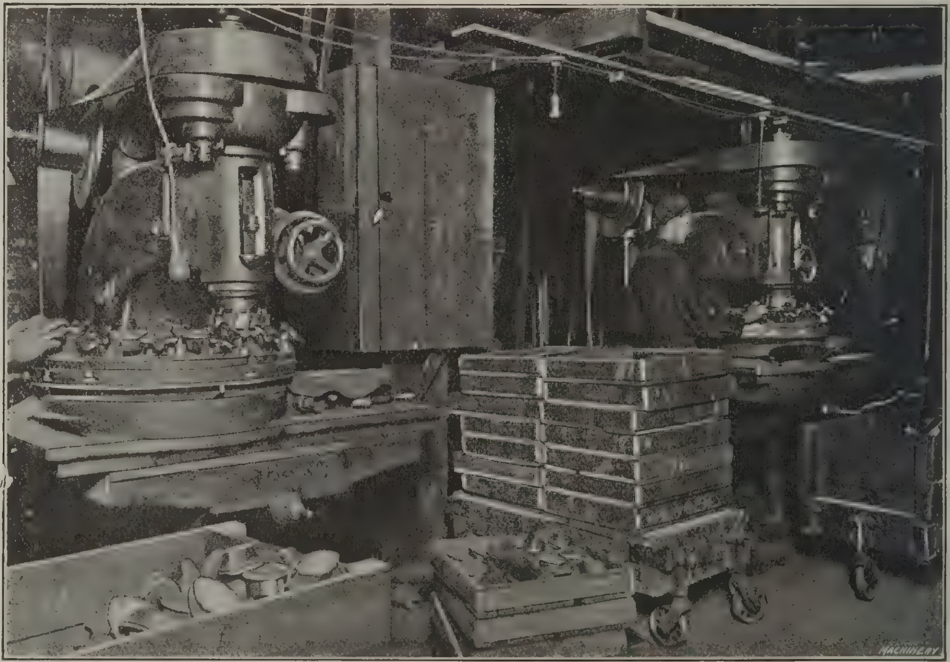

Fig. 2. The Improved Method of machining Sad Iron Bases

In operation, as the table rotates, the operator releases the clamping nut, removes the casting, brushes off the "seats," and inserts a rough casting, repeating this order as the castings are machined. It requires approximately 2½ minutes for the fix-

ture to make one revolution, and in this time 14 sad iron bases are machined, as against one sad iron base in 3 minutes by the old method. As before, ⅛ inch of material is removed from the base of the castings.

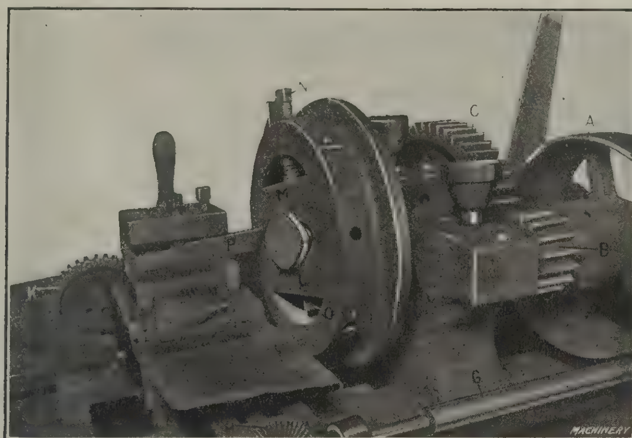

Fig. 3. View showing Construction of Old Chuck and Tool-slide

The machining of these sad iron bases is an excellent example of the application of rotary continuous milling fixtures to the manufacturing of castings in large quantities, and illustrates in a forceful manner the advance made in manufacturing methods. The fixtures used were designed and built by the Becker Milling Machine Co., Hyde Park, Mass.

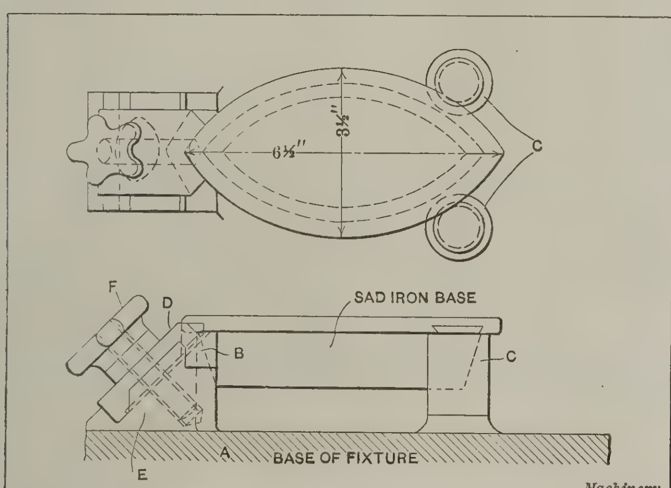

Fig. 4. Method of Clamping the Sad Iron Bases on the Continuous Rotary Milling Fixture

* * *

The Minneapolis, St. Paul & Sault Ste. Marie Railway has posted a notice in its car shops to the effect that employes will not be permitted to wear neckties or torn overalls while at work. This order has been issued with a view to reducing the danger of accidents in the shops, as many injuries have been due to the men having been drawn into machinery by their neckties or by ragged garments being entangled in the mechanism.

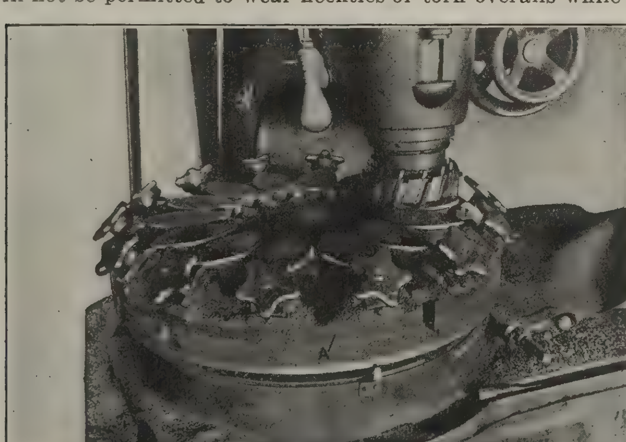

Fig. 5. Continuous Rotary Milling Fixture used on the Becker Vertical Milling Machines for holding the Sad Iron Bases while machining

FLUTING ANGULAR MILLING CUTTERS AND TAPERED REAMERS*†

BY GEORGE W. BURLEY‡

The "lands" which are formed on the teeth of all kinds of milling cutters and reamers, except those which are of the formed variety and those which are eccentrically relieved, whether cylindrical or conical, usually have a uniform width from one end of the cutter or reamer to the other. It is, of course, quite possible to arrange the cutter or reamer blank in the milling machine dividing head for the fluting or grooving operation so that the lands which are formed on the teeth will be tapered. The latter form of land is, however, never used in connection with axial and radial teeth, in good practice, and is very rarely used in connection with inclined teeth—that is, teeth on angular milling cutters and tapered reamers.

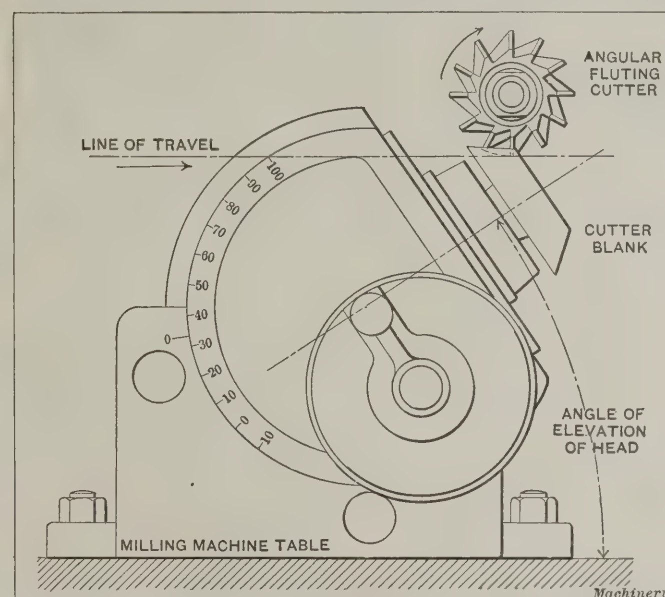

Fig. 1. Dividing Head set for Milling Teeth in Angular Cutter

For the formation of lands of uniform width on radial teeth on the sides and ends of cylindrical milling cutters and on inclined teeth on the conical surfaces of angular milling cutters and tapered reamers, it is necessary to set the axis of the cutter or reamer and, therefore, the axis of the dividing head, at a definite angle with respect to the horizontal axis of the dividing head and footstock centers. This angle depends upon several factors, which, in the case of angular milling cutters and tapered reamers, are enumerated and dealt with below. This angle is known as the "angle of elevation" of the dividing head (see Fig. 1). For cutters having radial teeth, the question of its determination and that of the depth of cut required was discussed in the November and December, 1911, numbers of MACHINERY by the present writer. The problem involving the determination of the values of this angle and the required depth of cut for angular cutters and tapered reamers is, however, more complicated, and is considered in the present article.

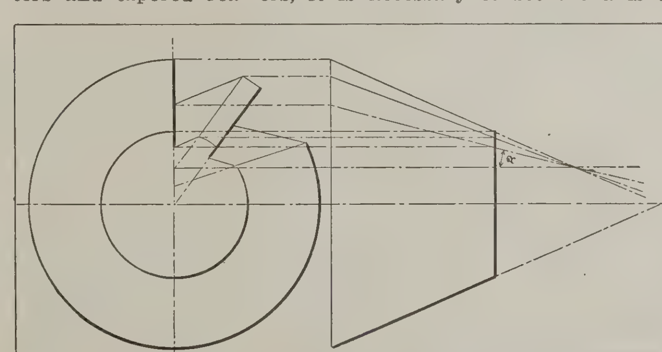

Fig. 2. Diagrammatical Representation of Principles involved in Milling Teeth in Angular Cutters

The lands on the teeth of any milling cutter or reamer are invariably finally formed in the grinding operation, but they can be—and usually are—initially formed in the operation of milling the flutes or grooves between the teeth. This reduces the duration and cost of both the milling and the grinding operations. This case is illustrated in Fig. 2, where angle a represents the angle of elevation of the indexing or dividing head. It could be conceived, however, that the fluting or grooving cutter and the cutter or reamer blank were so arranged with respect to each other that the cutter penetrated the blank to such a depth that each tooth was formed in the fluting operation with a sharp edge which possessed none of the characteristics of a land. This case is illustrated in Fig. 3, where the angle of elevation of the indexing or dividing head is represented by a. A comparison of Figs. 2 and 3 will show a marked difference between the two cases. In the first case, the bottom of the flute or groove does not pass through the apex of the cone of which the cutter or reamer blank is a frustum; in the second case, it does. It does not follow as a

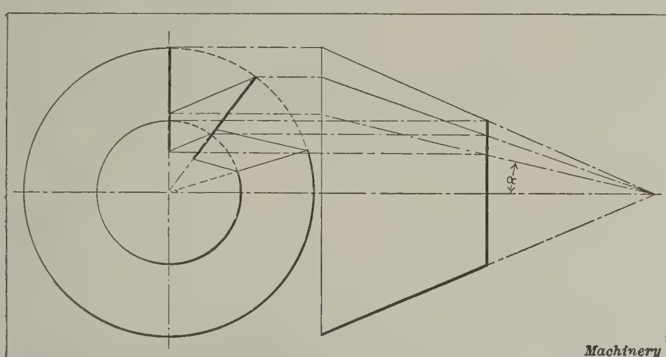

Fig. 3. Conditions obtaining if Tooth were milled to a Sharp Point

corollary, however, that, for similar conditions and dimensions (with the exception of the width of the land), the angles of elevation for the two cases are different, since it can be very readily demonstrated that the width of the land in any case has no influence upon the angle of elevation of the dividing head. This being the case, it is of no material importance which of the cases is considered for determining this angle; we shall, however, take the latter case (that is, the one involving no land-width), as it is the simpler of the two to treat.

There are two ways in which the angle of elevation can be determined. The first is the direct method, by means of which the value of a is calculated without any intermediate steps or operations. It is, however, an exceedingly complicated and cumbersome method, and not nearly as simple as the second one in its application. The second method involves three separate steps or operations: 1. The determination of the

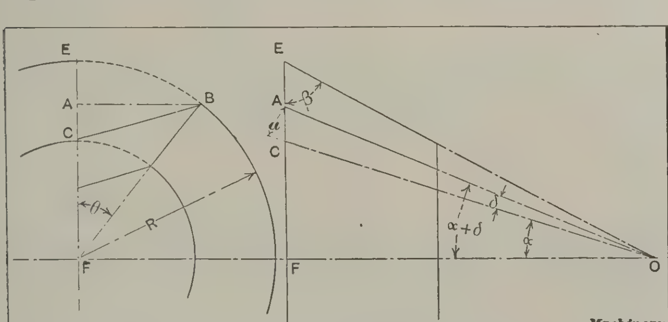

Fig. 4. Diagram for Deduction of Formula for finding Setting Angle for Dividing Head

value of the angle $(a + \delta)$, Fig. 4; 2. The calculation of the angle δ in the same figure; 3. The obtaining of the difference between these two angles.

The conditions of the problem are indicated in Fig. 4, in which O represents the vertex of the cone of which the blank is a part or frustum; FE and FB represent the radius of the large end of the blank and are, therefore, equal to each other; CO represents the bottom of the flute produced to the vertex O; and ECB represents the flute at the large end of the blank.

Let $R =$ the radius of large end of blank,

$\theta =$ tooth-angle of the blank (this angle is equal to 360 ÷ number of teeth to be milled in blank, the teeth being supposed to be spaced uniformly around the periphery of the blank),

$\beta =$ angle of blank (this angle is measured as indicated in Fig. 4),

$\gamma =$ angle of fluting cutter (this being assumed to be a single-angle cutter),

$a =$ angle of elevation of dividing head.

Then $FA = FB \cos\theta = R\cos\theta$, and

$$\tan(a+\delta) = \frac{FA}{FO} = \frac{R\cos\theta}{FO}.$$

Now, $\dfrac{FO}{FE} = \tan\beta = \dfrac{FO}{R}$; therefore $FO = R\tan\beta$. Hence

$$\tan(a+\delta) = \frac{R\cos\theta}{R\tan\beta} = \frac{\cos\theta}{\tan\beta} \qquad (1)$$

Since θ and β are known for any particular case, the values of $\cos\theta$ and $\tan\beta$ can be obtained from a table of trigonometrical ratios, and the value of $\tan(a+\delta)$ calculated, and the value of the angle $(a+\delta)$ obtained.

The second part of the process of finding the value of the angle of elevation of the head involves the determination of angle δ. In Fig. 4 $\sin\delta = \dfrac{a}{AO}$. Now, from an examination of Fig. 5, which is a section normal to the bottom of the flute or groove and passing through line AB, and by comparing it with Fig. 4, we see that $a = AB\cot\gamma$. Further,

$$AO = \frac{AF}{\sin(a+\delta)} = \frac{AB}{\sin(a+\delta)\tan\theta}. \text{ Therefore}$$

$$\sin\delta = \frac{AB\cot\gamma}{\dfrac{AB\cot\theta}{\sin(a+\delta)}} = \cot\gamma\tan\theta\sin(a+\delta) \qquad (2)$$

This expression will give the value of $\sin\delta$, since at this stage all the other quantities involved are obtainable from the given data, and from $\sin\delta$ the value of angle δ is obtained.

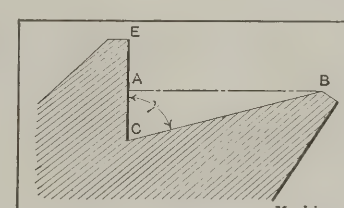

Fig. 5. Section Normal to Bottom of Tooth

It will now be observed that the values of the angles $(a + \delta)$ and δ can be calculated from the furnished data, and that their difference is the angle a required (the angle of elevation of the dividing head).

As the expressions above, however, are obviously altogether too cumbersome to admit of their use in ordinary machine shop practice, the accompanying Data Sheet Supplement has been prepared, giving the values of the angles of elevation of the dividing head for a large number of combinations of number of teeth to be milled in blank, angle of blank, and angle of fluting cutter. For any combination not provided for, the "simple proportion" method of determining the values of angle a from the values given in the tables will usually give a result sufficiently close for practical purposes. To illustrate this point, let us take the case of a cutter blank in which 15 teeth have to be milled, the angle of the blank (β) being 65 degrees, and the angle of the fluting cutter (γ) being 55 degrees. Consulting the tables and applying the "simple proportion" method in steps, we find that $a = 15$ degrees 58 minutes for this case, while if calculated by means of Equations (1) and (2), the value of the angle equals 16 degrees 3 minutes, the difference of 5 minutes being negligible, as it is not possible to set the dividing head spindle to within 10 minutes, in the majority of cases.

In addition to the angle of elevation of the dividing head, it is necessary to know the depth of cut required to form the width of land selected. This is also given in the accompanying Data Sheet Supplement. The mathematical deductions required to obtain the values given in the tables will be dealt with in the following.

TABLES VII AND VIII. ANGLE OF ELEVATION AND DEPTH OF CUT FOR FLUTING ANGULAR MILLING CUTTERS

In the foregoing the formulas required for calculating the angle to which to set the dividing head when milling angular cutters or taper reamers are given. The question of determining the depth of the cut required for any given width of land will now be dealt with. As will be shown in the following, the depth of cut required depends, among other factors, upon the selected width of land, and, therefore, a change in the depth of cut will cause a land of another width to be formed.

The conditions of this part of the problem are represented in Fig. 6. In this figure, W represents the width of the land. Now, as has already been explained in previous articles by the present writer in MACHINERY, the width of the land formed in the grinding operation is a straight-line quantity, but W in the figure is a circular width (that is, it is measured on the circumference of the blank circle). In the majority of cases, however, the difference between the two quantities is of infinitesimal dimensions and may, therefore, be neglected. Hence, in our treatment of the case, we shall assume that the two are equal. This circular land-width W (measured, in this

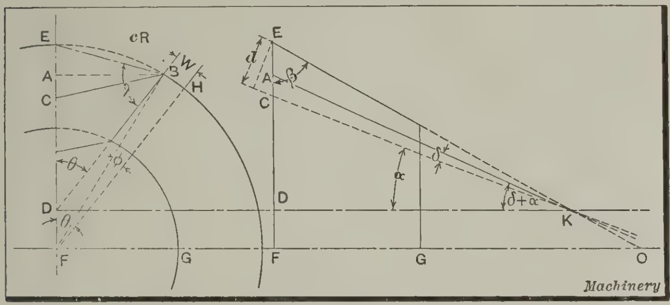

Fig. 6. Diagram for Deduction of Formula for finding Setting Angle for Dividing Head

instance, on the circumference of the circle representing the large end of the blank) subtends an angle ϕ at the center of the circle, the value of ϕ, in degrees, being $\frac{W}{R} \times 57.3$. The chord cR is the chord which subtends the angle $(\theta - \phi)$ at the center of the circle, the coefficient c being the length of this chord when $R = 1$. The line AB has already been referred to in connection with Figs. 4 and 5; d is the depth of cut required, and is measured in a direction normal to the bottom of the flute and from the edge of the blank.

An examination of Fig. 6 will show that:

$$d = EK \sin \{90 - (\alpha + \beta)\} = EK \cos(\alpha + \beta) \quad (3)$$

Now, $EK = \frac{ED}{\cos \beta}$, and $ED = \frac{cR \sin \lambda}{\sin \theta}$. But $\lambda = \left(90 - \frac{\theta + \phi}{2}\right)$;

hence, $\sin \lambda = \sin\left(90 - \frac{\theta + \phi}{2}\right) = \cos \frac{\theta + \phi}{2}$. Therefore:

$$EK = \frac{cR \cos \frac{\theta + \phi}{2}}{\cos \beta \sin \theta}, \text{ and}$$

$$d = \frac{cR \cos \frac{\theta + \phi}{2} \cos(\alpha + \beta)}{\cos \beta \sin \theta} = KR \quad (4)$$

in which

$$K = \frac{c \cos \frac{\theta + \phi}{2} \cos(\alpha + \beta)}{\cos \beta \sin \theta}$$

and is the depth of cut required for a blank having unit radius.

To make this expression of practical utility, the values of K corresponding to the combinations of number of teeth N, and angles β and γ selected in the case of the angle of elevation of the dividing head, and several values of $\frac{W}{R}$ are given in Tables V, VI, VII and VIII, along with the angles of elevation of the head. Intermediate values (that is, values not covered by the combinations adopted in these tables, are obtainable within very close limits by means of the "simple proportion" method, as in the case of the angle of elevation of the head.

To illustrate the application of this method, let us take the case of a cutter blank in which 20 teeth have to be milled, the angle of the blank (β) being 45 degrees, and the angle of the fluting cutter (γ) being 60 degrees. Let the selected value of $\frac{W}{R}$ be 0.030. Then the depth for unit radius, when $\frac{W}{R} = 0.020$, equals 0.203 inch; and when $\frac{W}{R} = 0.040$, the depth equals 0.190 inch. Hence, when $\frac{W}{R} = 0.030$, the depth for unit radius equals

$$\frac{0.203 + 0.190}{2} = 0.1965 \text{ inch.}$$

The radius of the blank is invariably made a trifle larger than the radius of the finished cutter or reamer in order to allow for grinding after hardening, in which case, theoretically, it is necessary to make an allowance for the difference between the two radii in the expression giving the depth of cut. The modified expression is:

$$d = KR + (R_1 - R) \cos \alpha$$

in which R_1 = the radius of the large end of the blank, and R = the radius of the large end of the finished cutter or reamer.

METHOD OF PRODUCING SOUND INGOTS

The trouble experienced by railroads with broken rails, especially in countries where low temperatures prevail in winter, has demonstrated the necessity of producing sound rails. To produce sound rails means that the ingots from which the rails are made must also be quite sound and free from piping, segregation and blow-holes. Unless the ingots fulfill these requisites, trouble is bound to be experienced with the rails rolled from them.

The defects mentioned are caused by the conditions that existed in the ingot during the cooling process. Trouble from piping is caused by unequal contraction of the metal during cooling. This is due to the fact that the outer sections solidify first. Solidification continues little by little, the center being the last to reach the solid form. This means that an unequal degree of contraction takes place in the ingot, and as the space made void by this contraction is filled by liquid metal flowing down from the top, a cavity or "pipe" is formed in the upper section.

It is an established fact that defective ingots cannot be rolled into sound rails. The method of doing away with defects from piping employed by Sir Robert Hadfield and described in a paper read before the September 1912 meeting of the Iron and Steel Institute, consists of placing charcoal or other combustible material on top of the ingot mold after it has been filled. A layer of cupola slag is placed between the charcoal and the molten steel in order to protect the latter from the oxidizing effect of a blast of air which is directed on top of the ingot to facilitate the combustion of the charcoal. The ingot mold is fitted with a sand top, holding a supply of metal which is kept in a molten condition by the heat generated by the charcoal. This molten metal descends in the mold as contraction takes place and eliminates any tendency toward piping which would otherwise result from the contraction that takes place during cooling. The addition of small quantities of metallic aluminum tend to "quiet the metal", that is to say the aluminum combines with oxygen which is present and carries it away in the form of slag. This reduces the tendency toward the formation of blow-holes. Fortunately it has been found that a remedy which overcomes the tendency toward piping also tends to check the formation of blow-holes or segregated sections. Consequently ingots produced according to this process are particularly free from defects, and the additional expense is more than offset by the reduction in the quantity of material which must be discarded during subsequent processes.

RELATION OF PRICE OF TOOL STEEL TO MANUFACTURING COSTS

BY D. G. CLARK*

A short time ago we received an order from an up-to-date concern, bearing this notation: "This steel, which costs twice as much, must give at least double the production of our present steel in the operation in which it is to be used, otherwise it will be returned." The buyer in this concern was one of the men who believe that if one tool steel costs fifty per cent more per pound than another, it must do fifty per cent more work to justify the price. As a matter of fact, if one steel does five per cent more work than another it is well worth fifty per cent more per pound on all usual operations. There are many ways of proving this. One is to take any machine in the shop and learn the relation of tool cost to total costs. For illustration, we have selected a lathe using tools made from 1½ by ¾ inch steel. How much high-speed steel is used a day? Our observations, estimates and averages show that the daily consumption is one-twelfth pound of high-speed steel on the average lathe, doing fairly hard work at a good speed. This is based on work requiring the tool to be ground five or six times a day. If the tools cut all day on one grinding it indicates that they are cutting considerably below capacity, although this is sometimes necessary owing to local conditions. The one-twelfth pound daily consumption of steel is arrived at in the following way:

High-speed Steel used Daily on 20-inch Lathe

Size of tool: 1½ by ¾ inches. Average number of grindings: six per day.

Steel ground away each grinding......	1/32 inch
Steel ground away each day (six grindings)	3/16 inch
Steel ground away each week (six days)	1 inch (approx.)

Then the tool needs redressing. In redressing and retempering, a small piece of steel is cut off. Making liberal allowance, this waste is about one-half inch of steel.

The waste of steel in redressing is..............	½ inch
The amount of steel ground away is (see above)	1 inch
The weekly consumption of steel................	1½ inches

One-and-one-half lineal inches of 1½ by ¾ inch high-speed steel weighs one-half pound. The daily consumption, therefore, is one-sixth of one-half pound, or one-twelfth pound.

The Daily Cost of Tool Steel

On the basis of one-twelfth pound steel consumption per day, if equal quantities were used:

High grade high-speed steel at 71 cents per pound costs, per day..	$0.06
Cheap high-speed steel at 48 cents per pound costs, per day	.04
Increased first cost of higher priced steel, per day......	$0.02

The Cost of Operating

On a lathe such as we are using for illustration,

The machinist's hourly rate, about.....................	$0.36
The overhead (including power)......................	.24
The total hourly rate..................................	$0.60
The day rate (eight hours)...........................	$4.80

The Value of the Product

If the man operating the lathe which we are using for illustration turns out 100 units of work daily, each piece costs the manufacturer 1/100 of $4.80 or 4.8 cents, and just that much value is produced. If the higher priced steel enables the machinist to turn out one piece more daily, thus increasing the output only one per cent, we have the following results:

Value of one extra piece produced....................	$0.048
Increased first cost of the steel.......................	.020
Net daily profit on one per cent increase..............	$0.028

In this case a one per cent increase would warrant buying a good grade of steel costing fifty per cent more than cheap steel.

With a steel like "Blue Chip," for example, increases in production as high as fifty per cent or one hundred per cent are often secured, but the object of this article is to show that a five per cent increase in production justifies paying much more than a fifty per cent increase in first cost.

Taking the same illustration from another point of view: With the higher priced steel at 71 cents per pound,

The man's time per day.............................	$2.88
The "overhead" per day............................	1.92
Steel per day..	0.06
Daily total..	$4.86

With cheap steel at 48 cents per pound,

The man's time per day...........................	2.88
The "overhead" per day............................	1.92
Steel per day..	0.04
Daily total...	$4.84

The total daily cost has been increased less than one-half of one per cent; one-half of one per cent of $4.84=2.4 cents. Therefore if the higher priced steel does one-half of one per cent more work, it is the cheapest, although the price per pound may be fifty per cent higher than the steel formerly used.

Saving in Grinding

There is another point of view from which the price of tool steel should be considered, and that is the saving in grinding. Some tool steel users think that if the steel costs twice as much, it must require grinding only one-half as many times, but in the foregoing illustration, if one grinding is saved in two days, it justifies paying fifty per cent more for the steel. We arrive at this conclusion through the following: We have found that sixty cents an hour is a conservative estimate of the cost of a man's time and the overhead expense. On this basis every grinding which requires about five minutes means a loss of time and production worth five cents. The excess first cost of steel at seventy-one cents, as compared with a forty-eight-cent steel on the machine we are using for illustration, amounts to two cents a day. Therefore, if tools made from the higher priced steel save one grinding in two days, they warrant an increase of fifty per cent in the price per pound.

In addition to the profit and saving resulting from increased production and fewer grindings, there are also secondary savings to be considered. For instance, tools made from the higher priced steel will require redressing and rehardening less frequently, and the cost department knows what this means in the way of economy. Another saving results through a reduction in the amount of steel used. This has not been brought into our figures, but it should be considered in discussing tool steel costs. Less of the high-priced steel will be required than is the case where cheap steels are used.

Another important saving that is often forgotten, and which cannot be computed, is the time saved on break-down or emergency jobs. There are times in many shops when the management would gladly pay as much as the monthly tool steel bill to save an hour on a repair part, the lack of which holds up a large shipment, or stops work throughout the shop.

A number of minor savings have not been mentioned, but they are not needed to prove the wisdom of paying fifty per cent more for a steel which does five per cent more work. In conclusion, it may be stated that this method of considering tool steel costs may be applied on any machine, regardless of the kind of steel used. In nearly every case the higher priced steel, whether in ordinary tool steel grades or in high-speed steel grades, will be found cheapest if it brings about even a slight increase in the efficiency of cutting tools.

[The indirect relation of the cost of the tools of production to the cost of production so clearly set forth by Mr. Clark in the foregoing, applies all along the line. The first cost of a machine is of little importance in comparison with its productive capacity during its lifetime. A lathe costing $1000 may in the course of ten years, earn $10,000 for the shop in which it is used, while another of the same nominal capacity but of superior design and workmanship, costing say $1100, might earn $12,500 in the same period, or sufficiently more than the other to wipe out the original cost and the interest on the investment.—EDITOR.]

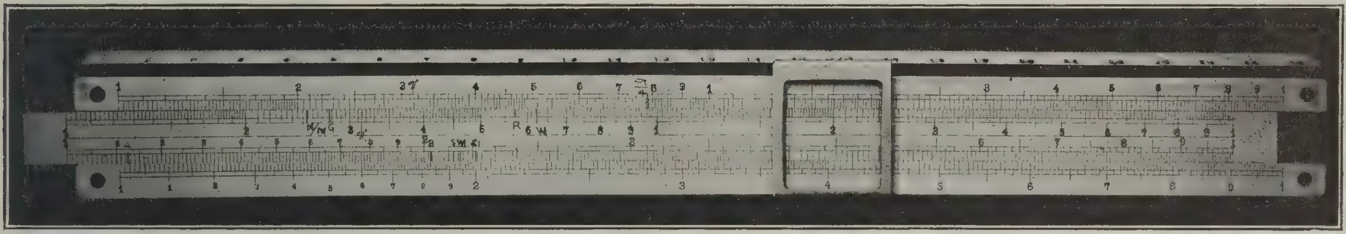
SLIDE-RULE CONSTANTS

BY A. LAURENS

The illustration which appears in connection with this description shows the writer's slide-rule on which several useful constants have been laid out. These constants refer to quantities which are frequently used by designers and estimators, and their use enables the weight of disks or rings of various metals to be rapidly determined. The metals in question are indicated on the rule by the following letters laid out on scale 3 of the slide-rule: *S*, for steel; *WI*, for wrought iron; *CI*, for cast iron; and *B* for brass. On the same scale there is marked a constant *V* that is used to determine the volume of disks or rings. In using the rule, on which these constants are marked, to obtain the weight of a disk or ring of the metal in question, it is only necessary to bring the symbol for the particular metal over the figure for diameter on scale 4 of the rule. The required weight or volume is then read on scale 1 of the rule above the thickness of the disk on scale 2. These results will be found accurate enough for almost any class of work and this method of calculation is far more rapid than the customary arithmetical process.

To illustrate the use of these constants, the reader is referred to the setting of the rule shown herewith. Here it will be seen that the constant for cast iron is set for a disk 20 inches in diameter. To get the weight of such a disk 3 inches thick, the reading of 245 pounds is obtained on scale 1 directly above the figure 3 on scale 2. To obtain the volume of a disk 20 inches in diameter and 3 inches thick, the constant *V* on scale 3 would be brought up to the figure 20 on scale 4. The volume of 944 cubic inches is then read on scale 1 over the figure 3 on scale 2. For the sake of checking the accuracy of this method, the same problem is carried through in the ordinary way. The weight of this disk will be $\frac{\pi D^2}{4} \times$ thickness $\times$ weight per cubic inch of cast iron. The weight of a cubic inch of cast iron is 0.26 pounds and substituting the other known values, a figure of 245.3 pounds is obtained for the weight of the disk. The volume of the disk is $\frac{\pi D^2}{4}$ $\times$ thickness $=$ 943 cubic inches. These figures correspond closely enough for all practical purposes with the one obtained by using the constants. Even allowing that the arithmetical method can be worked out on a slide-rule, it will be granted that such a method takes longer than the one where the constants are used. With the constants, only one setting of the rule is required, and after this setting has been made any number of weights or volumes can be read off at once. In obtaining the weight or volume of a ring of metal, the process has to be repeated, and one reading subtracted from the other, the method being that of finding the difference in weight or volume between two disks of metal of the outer and inner diameters of the ring.

It will be seen that several other constants have been laid out on scale 2 of the rule. These are $M/M = 25.4$ which represents the number of millimeters in an inch. $G = 277$, which is the number of cubic inches in a gallon. This is the number of cubic inches in the British Imperial gallon and for the use of American engineers it would be better to give this figure a value of 231, which represents the number of cubic inches in the standard U. S. gallon. $R = 57.3$, which is the number of degrees in a radian. $W = 62.3$, which is the number of pounds per cubic foot of water. These are constants which engineers frequently need to use, and having them marked directly on the face of the rule saves a lot of time.



Slide-rule laid out with Some Useful Constants

HOW A LITTLE SHOP GREW

BY A. P. PRESS

One evening we were out on the back door-step, and Billy, our next-door neighbor, came to the fence and called us over. Now, we had known Billy a long while. He was a pretty good fellow. He didn't drink or use any red paint, had a wife and two kids who, although they used to stone our cat once in a while, were pretty good boys after all. Billy had learned his trade with us some six years ago, and then he got out and went with the B. & H. Co., and had been with them ever since, and while we knew that he had been tinkering down cellar we were kind of surprised at what he wanted.

"Say, Mr. Press, haven't you got an attic over in your shop there that isn't working very hard?"

"Yes, Billy, I guess so."

"Well, I've been doing a little manufacturing on the side the last year. In the summer time I did it down cellar, and last winter I moved it up in the bed-room. Now it's getting kind of thick, and I thought perhaps you could let me have that back attic, and put all the junk up there."

"That's all right, Billy," we said. "Go ahead and put it in. You probably won't need any power, but if you do we'll cut a hole through the floor and run a belt up. What do you want to run?"

"Oh, nothing much; just a power press and a drill press, and possibly a lathe."

"Well, Billy, go ahead. The attic is not very big, but if you can stand it we can."

So Billy went ahead. He moved in one Saturday afternoon, and from then on there was more or less noise from the back attic that indicated that Billy was working. We didn't butt in on him, but when he had been there about six months we took a notion one evening to go in and see him, and we were surprised. He had a nice little lathe, drill press, power press and foot press, all in that 10 by 14 attic, and he was turning out some of the neatest little tool attachments we had ever seen.

"Well, Billy, where did you get those ideas?"

"Oh, I kind of picked them up, and put them through the patent office, and I suppose they are mine now."

We went away and let Billy alone. Six months more passed by, and Billy came around one night and said:

"Well, Mr. Press, I guess I'll have to move out next month."

"Why, how's that?"

"Well, you see, it's kind of crowded, and so I'm going to build a little shop in the back-yard."

So Billy built his "little shop" (it was about 20 by 40 feet) and moved his tools in. There was a smart looking boy working steady every day, but Billy was only there evenings, for he still held his position with the B. & H., where he had risen to be master mechanic, and was drawing a good salary.

For a whole year we watched Billy nights and Saturday afternoons (the place was shut tighter than a drum Sundays) and one Monday we noticed Billy hanging around the place all day. The next morning we happened to see him over the fence, and sang out to him.

"How's that, aren't you working this week?"

"No," said Billy, "not this week. You see it was like this. The orders were piling in on me for those little tool attachments, and I got so many ahead that I was kind of worried. So I told them down to the factory that I wanted two weeks off, and while they put up an awful howl, I said it was either that or fire me. They didn't want to fire me, so they gave me the two weeks. I guess I will catch up in that time."

Two weeks passed, and we saw Billy again.

"Say, Mr. Press, you don't know where I could get a good man to take my job down to the B. & H., do you?"

"Why, what's the matter?"

"I thought I could catch up with my orders here in two weeks, but instead of that I'm farther behind than I was when I came out. So I went down and told them, and they put it up to me good and plenty that I either had to go back or else get them a man to take my job, so I'm looking for the other man."

Well, to make a long story short, Billy found the "other man." He has been out in the little shop nearly a year now, and it has been running 313 days. Sundays and Christmas are the only days that Billy doesn't work, and from the ink stains that I saw on Mrs. Billy's fingers the other day, I should say that she runs the bookkeeping end of the job.

We were in to see him not long ago (our power was shut down and we wanted to grind a chisel) and he had the nicest little shop that we have seen for a long time. It was crowded, and Billy says:

"I can't seem to get caught up on the work, and the only thing that I can see is to add on some floor space somewhere. I haven't much money, but I went and told all my customers just how it is, that I've got to turn my money over pretty often to make both ends meet, so as to take care of Mrs. Billy and the kids, and they have all done fine."

It doesn't take much of a vision to look into the future (not very far, either) and see Billy holding down an arm chair with a roll top desk, and with the business increasing to support the same.

Now, if any of you boys are planning to follow in Billy's footsteps, and want the secret of his success, it is very easy to get. It is work, work hard, and then work some more. We will try and keep tabs on Billy for at least a year or so more and tell you about him again. If you are a young man it will do you good. If you are an old fellow it wont hurt you any.

CROSS-SLIDE REAMING ATTACHMENT FOR THE CLEVELAND PLAIN AUTOMATIC

It is generally recognized that the plain type of automatic screw machine built by the Cleveland Automatic Machine Co., Cleveland, O., lends itself admirably to the rapid production of parts requiring the use of only one turret tool; hence in some shops this type of machine is confined to work requiring the use of one turret tool exclusively. The chief advantage gained in using the plain type of machine is that most of the idle movements common to the turret type are eliminated, thus cutting down the production time considerably.

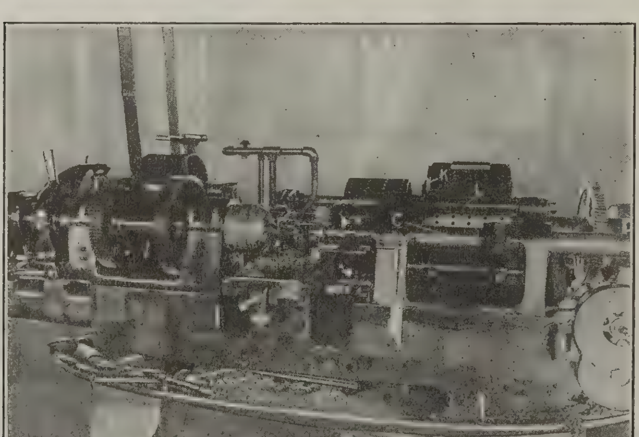

Fig. 1. Method of Gaging Work to Length

The piece shown in Fig. 2 is a good example of work, which with a little thought on the part of the designer can be produced economically on the plain type of machine. As can be seen, this piece, if made on the turret machine, would require three turret tools: stop, drill and reamer.

The method of "tooling" the plain machine for producing this piece is shown in Figs. 1 and 3. Here a drill A is held in a split holder B, the latter being retained in the tailstock spindle C. Enveloping the tailstock spindle is a collar D, which is provided with a notched lug fitting the bent end of the push-rod E.

The reamer F is held in a spindle G, which is a sliding fit in the bracket H clamped to the front cross-slide. Fastened to the front end of the spindle G, is an arm I, which extends down and is provided with a hole through which the push-rod E passes. This push-rod is threaded on the end passing through the arm, and is provided with adjusting nuts located on either side of the arm. These nuts are used for adjusting

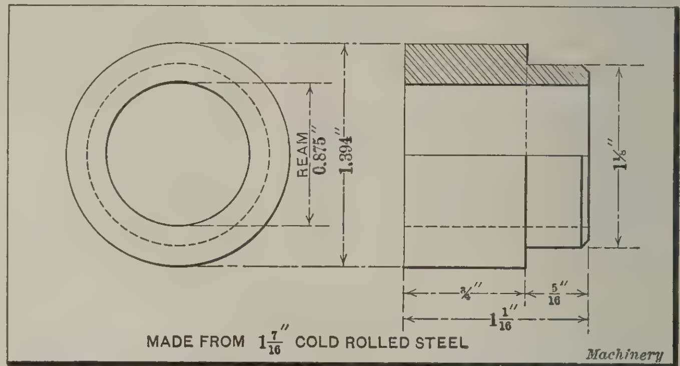

Fig. 2. Type of Work profitably made on Cleveland Plain Automatic

the push-rod, so that its bent end will always enter the slot in the collar D, the coil spring S always returning this rod to the same position, ready to be engaged again when the cross-slide is advanced to bring the reamer into position.

In operation, the stock is fed out, and is gaged to length by the swinging stop J, which is operated by a cam block K in Fig. 1. This stop is returned to the "up position" by a twisted spring L. After the stock is gaged to length, the cross-slide is advanced and the work turned to the required shape and diameter by a flat forming tool M. The cross-slide

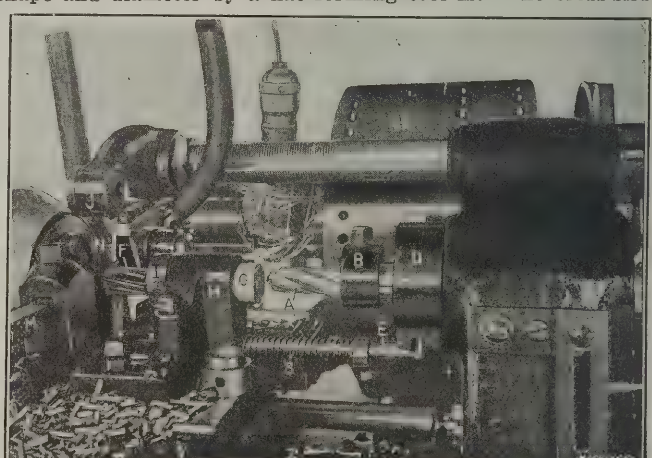

Fig. 3. The Method of "Tooling" the Machine

then retreats, and the tailstock spindle carrying the 0.865-inch drill A is advanced, producing the hole.

The tailstock spindle now retreats into the position shown in Fig. 3; then the cross-slide advances and the bent end of the push-rod engages with the slot in the collar. The tailstock spindle then advances and as it is connected with the reamer holder by the push-rod, it follows that the 0.875-inch reamer is forced into the work.

Before the reamer has finished cutting, the rear cross-slide is advanced, carrying the cut-off blade N, which severs the completed piece from the bar. While the work is being severed, the tailstock spindle recedes, and as it reaches the "back position", the push-rod is disconnected from the collar by the cross-slide dropping back, thus clearing the machine ready for this cycle of operations to be repeated.

The cams are timed on all of the various drums, so that each tool just clears, thus cutting down the idle time to a minimum. The work is rotated, in a forward direction, at 334 R. P. M., and it requires 84 seconds to complete one piece. The feeds given the various tools are:

Drill	0.008 inch per revolution,
Reamer	0.012 inch per revolution,
Form	0.003 inch per revolution,
Cut-off	0.003 inch per revolution.

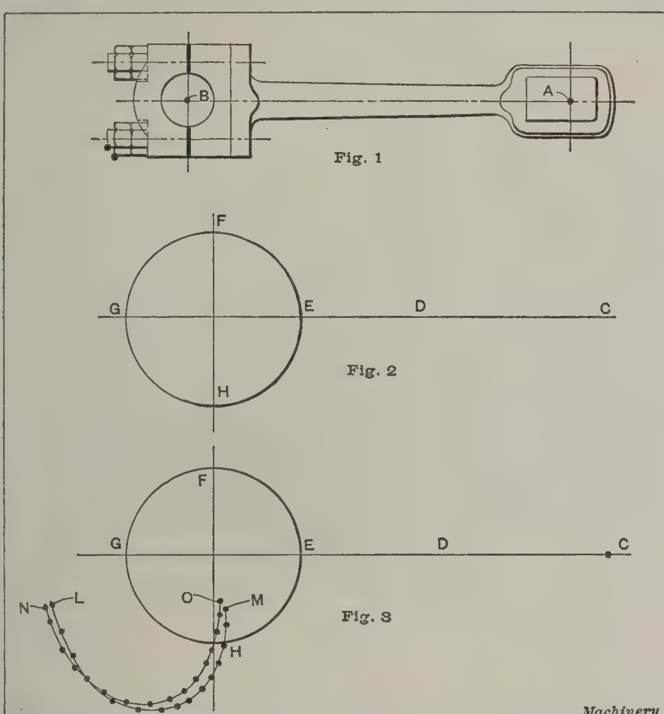
SOME PROBLEMS SOLVED BY THE USE OF TRACING CLOTH

BY JOHN S. MYERS*

The designer sometimes wastes considerable time trying to determine whether he has allowed proper clearance for a moving part. The method of laying out the part in several different positions in an attempt to determine whether there is any interference is the longest way around. Some draftsmen draw a circle or a straight line which is termed the "clearance line" and to which they work. However, if properly developed, the actual clearance boundary is often a peculiar curve which differs considerably from a circle or a straight line. Methods of this kind often compel the erector to get the required clearance by chipping off ribs which are actually needed for strength. The cost is increased, the designer loses prestige, and there is annoyance all around.

The best and simplest way for investigating the clearance requirements is to roughly trace the moving part on transparent paper or tracing cloth and move it over the layout with a motion similar to that of the moving part. In this way accurate clearance boundaries may be quickly established, and while this method is quite generally known, the writer believes that its value is not sufficiently appreciated, and that advantage is not taken of this method as often as would be advisable. The following will illustrate its use.



Figs. 1 to 3. Methods used in Investigating the Clearance Requirements by Means of Tracing Cloth

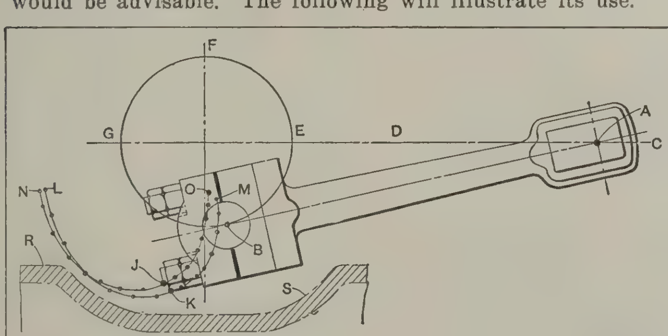


Fig. 4. The Clearance Determined

In Fig. 1 is shown a connecting-rod, the clearance for the crank-end of which is to be determined. First draw the lines indicated in Fig. 2 on the drawing paper. Here the line *CD* represents the path of point *A*, Fig. 1, while circle *EFGH* represents the path of point *B*. The connecting-rod in Fig. 1 is drawn on tracing cloth, and this may now be laid on top of the lines drawn on the drawing paper in Fig. 2, as indicated by Fig. 4. The connecting-rod on the tracing cloth is then moved about, point *A* being kept on the line *CD* and point *B* on the circle *EFG*. The points *J* and *K* then describe the clearance curves required at the further end. These can be pricked with a pin, and the curves *LM* and *NO* drawn through the points thus determined.

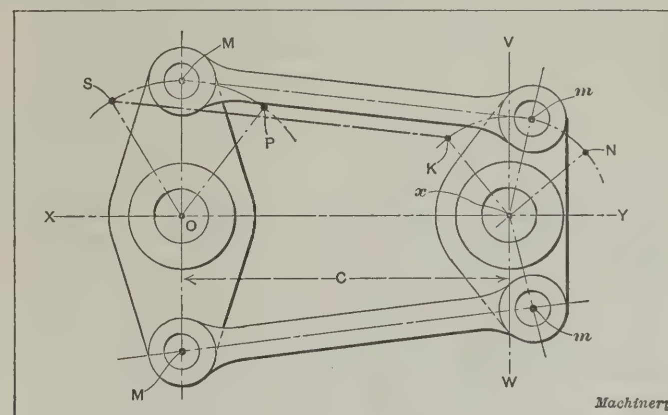

Fig. 5. A Mechanism involving a Complex Geometrical Problem

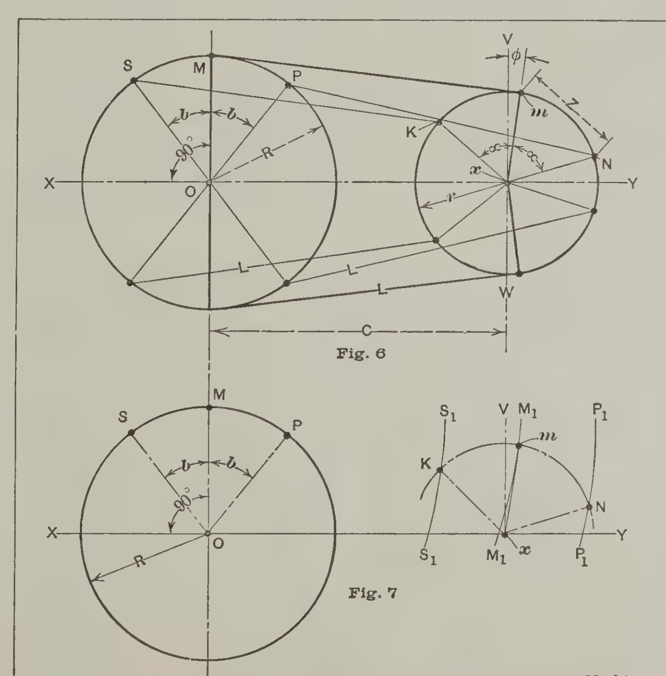
Another kink which can be made use of in connection with tracing cloth may be of interest. In making the blueprint from which Fig. 4 is reproduced, the writer did not wish to redraw the complete connecting-rod, yet it had to be shown to make the illustration complete. The method pursued was as follows: Fig. 1 was laid on top of Fig. 2 and the points of curves *LM* and *NO* pricked through and the curves drawn, which resulted in a drawing as shown in Fig. 3. The tracing in Fig. 1 was now placed on top of the tracing of Fig. 3, in correct position, and secured to it by adhesive tape; then a blueprint was made with sufficient extra exposure to allow for the double thickness of tracing cloth. The result then was a blueprint as indicated by the illustration shown in Fig. 4, to which, of course, was later added the dash-dotted lines showing the bed of the engine. The white spots left on the blueprint by the adhesive tape can be trimmed off and all evidence of the use of two tracings disappears. The contour of the bed casting *RS*, Fig. 4, is shown merely to indicate the reason for determining the clearance lines. The case chosen for illustration is a simple one, but the methods used are applicable to a wide range of work.



Figs. 6 and 7. Method of Solving the Geometrical Problem involved in the Linkage in Fig. 5

The draftsman also sometimes meets with geometrical problems which would prove difficult to a professor of mathematics; yet he must find some quick and practical solution.

* Address: 2456 Almond St., Philadelphia, Pa.

By the use of a piece of tracing cloth the designer may often solve problems which mathematically are so involved as to seem almost hopeless. Such a case is given in the following.

In the linkage shown in Fig. 5, point M oscillates between points S and P, being actuated by point m moving along curve KmN. The object of the construction is to obtain a toggle joint action as point m approaches points K and N. A skeleton diagram is shown in Fig. 6. Point O is a fixed center, while, due to the angularity of the links Mm, point x moves on line XY, making center distance C a variable quantity. It was found that by putting point m at some angular position ϕ away from line VW, the movement of point x along line XY could be very materially reduced. The problem then was to determine a value for ϕ such that the movement of point x would be a minimum. The mathematical solution by the aid of calculus seemed very difficult, and after some experimenting it was decided that if center distance C was the same for the central position of the links Mm as for the extreme positions SK and PN, the movement of point x would be reduced to practically a minimum. The problem then reduced itself to this: R, r and L being known, find values of C, α, and ϕ such that C will be constant for positions OS, OM and OP of the linkage. The solution is as follows:

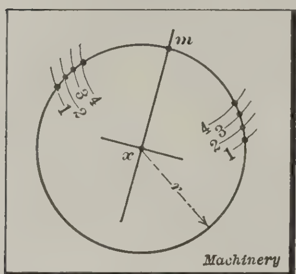


Fig. 8. The Lay-out made on Tracing Cloth

With radius R draw the circle in Fig. 7 and lay out the maximum angular movement b, thus locating points S, M and P. Draw XY through O perpendicular to OM. With radius L draw arcs S_1S_1, M_1M_1, and P_1P_1, S, M and P being their respective centers. On a transparent sheet draw a circle of radius r, x being its center, see Fig. 8. Choose some point on this circle, as m, and draw (with any convenient radius known to exceed Z in Fig. 6) the arcs 1, 1; then with slightly smaller radii draw arcs 2, 2; 3, 3; 4, 4; etc. Number these arcs 1, 2, 3, 4, etc.

Lay Fig. 8 on top of Fig. 7 and shift it around until, with point m lying on arc M_1M_1 and x lying on line XY, a position is found in which two similarly numbered points such as 1, 1, 2, 2, or 3, 3 lie upon arcs S_1S_1 and P_1P_1. When this position is found, prick through these numbered points, and also through points x and m; they will then represent the points similarly marked in Fig. 6. Mark these points found on Fig. 7, and draw lines xK, xm, xN, and xV, the latter being perpendicular to XY. Now $Ox = C$, angle $mxK = \alpha$, and angle $mxV = \phi$, the three unknown quantities which were to be found.

With a value of ϕ determined by the above method, the center distance C will be exactly the same in value for the links in position Mm, SK, or PN, but for any intermediate position, C will be slightly increased, or if angle b be exceeded, C will decrease.

There are a great number of difficult problems which may be solved in a somewhat similar manner by the employment of a little ingenuity. The writer's object in presenting the foregoing examples has simply been to call attention to the methods available and the value of a piece of tracing cloth.

DIMENSIONS OF LEAD PIPE

BY S. E. FERRY*

Some time ago I had occasion to use some lead pipe, and as it was necessary to know the inside as well as the outside diameters of the pipe (the space being limited) and the safe working pressures, I sought for the information in various books, but was surprised to find that the data was not available in the references at hand. After considerable hunting through the lead manufacturers' and plumbers' supply books, I was able to compile the accompanying table, which gives the outside diameter, inside diameter, thickness, weight per foot, approximate bursting pressure and safe working pressure of lead pipe from ⅜ inch to 2 inches inside diameter, in double extra strong, strong, medium and light weights.

DIMENSIONS OF LEAD PIPE

Inside Diameter	Outside Diameter	Thickness	Weight per Foot		Approximate Bursting Pressure in Pounds per Square Inch	Safe Working Pressure in Pounds per Square Inch	Commercial Designations		Inside Diameter	Outside Diameter	Thickness	Weight per Foot		Approximate Bursting Pressure in Pounds per Square Inch	Safe Working Pressure in Pounds per Square Inch	Commercial Designations

MULTIPLE-SHOULDER SHAFT TURNING ON THE CLEVELAND AUTOMATIC

An excellent example of multiple shoulder shaft turning in a Cleveland plain type automatic screw machine, is shown in Fig. 2. As can be seen, this shaft has six different diameters —three on each end. All of these various diameters are turned and the shaft completed in one operation. The end of the shaft next to the chuck is turned by a cross-slide tool arrangement carrying three turning tools, and operated transversely by the tailstock spindle, as shown in Figs. 1 and 3.

By referring to Fig. 1 it will be seen that a long connecting-rod *A* is held free to slide in an arm *B*, which is clamped to the tailstock spindle *C*. The rear end of this connecting-rod is threaded and furnished with check-nuts, the function of which will be explained later.

The cross-slide arrangement consists of a block *D*, fastened to the T-slot of the regular cross-slide and provided with a dovetailed top face to which an auxiliary top-slide *E* is fitted. This slide is furnished with a gib to compensate for wear, and is machined to retain the three tool-holders *F*, which can be adjusted so as to bring the shoulders on the work the required distance apart.

The end of the shaft facing the tailstock spindle is turned by a box-tool carrying three cutters and provided with roller

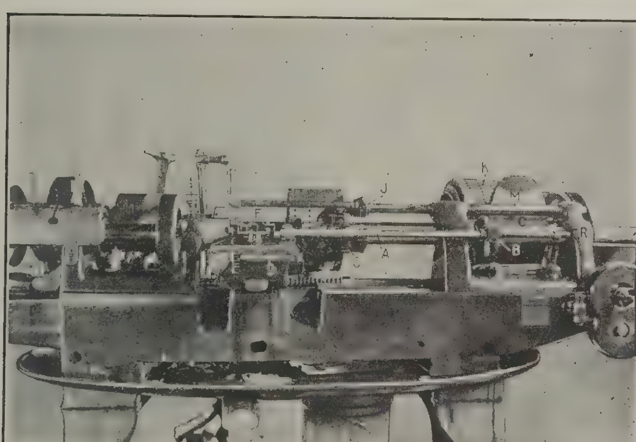

Fig. 1. Turning a Multiple Shoulder Shaft on the Cleveland Plain Automatic

supports to steady the work, as in Fig. 3. This box-tool *G* has a shank which is held in the regular manner in the tailstock spindle. The turning tools are retained in holders *I*, which can be adjusted along the body of the box-tool to the required positions.

In operation, the stock is fed out by a special cam on the stock-feed drum, and at the same time, the swinging stop *J* is brought down to gage the stock to length by a cam on drum *K*, see Fig. 1. When the chuck closes, the stop *J* is returned to the "up position" by the twisted spring *M*. The box-tool is now advanced, bringing the first tool *N*, Fig. 2, into operation, and at the same instant the regular cross-slide is advanced, feeding the tools *O*, *P*, and *Q* in to the proper depth. The cross-slide then retreats, and remains stationary with the tools clear of the work until the arm *B* approaches the check-nuts on the connecting-rod *A*. Just as this takes place, the regular cross-slide is again advanced, bringing the turning tools in to the correct depth.

The cross-slide turning tools which are now ready to turn the work to the required diameter, are advanced longitudinally on the work when the advancing arm *B* contacts with the check-nuts. The connecting-rod *A*, which acts as a link joining the tailstock spindle and auxiliary slide *E*, is pivotally connected to the latter. When the roll reaches the end of the lobe of the tailstock spindle operating cam, the spindle is returned by a spring, but does not carry the top-slide *E* with it until the arm *B* reaches the check-nuts *R*. By this time the regular cross-slide has withdrawn the tools from the work, thus clearing the machine for the finished piece to be severed from the bar by the cut-off blade *S*, held on the rear cross-slide.

The material from which this shaft is made is cold-rolled steel 1⅛ inch in diameter. The turning tools are operated

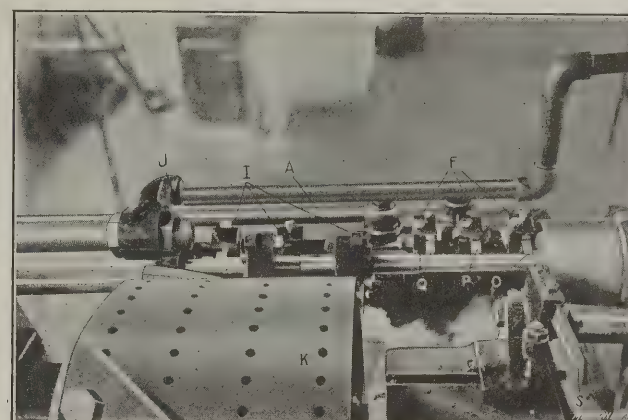

Fig. 3. Arrangement of Tools and of Adjustable Stop

at a surface speed of approximately 85 feet per minute, and finish the bar to the required diameter in one cut. The box-tool cutters when working alone, are advanced at a rate of 0.008 inch per revolution. The cross-slide tools when being fed in to the desired depth, receive a feed of 0.002 inch per revolution, and when the box-tool and cross-slide tools are working together, the rate of advance is 0.006 inch per revolution. The work is cut off with a feed of 0.004 inch per revolution. This shaft, which is 16 1/16 inches long, is completed in 5½ minutes. D. T. H.

LARGEST TESTING MACHINE IN THE WORLD

The issue of the *Engineering Record* for September 28 contains an interesting description of what is believed to be the largest testing machine in the world. It was designed by Mr. Tinius Olsen of Philadelphia, and has a capacity of 10,000,000 pounds. The machine was built for the structural materials testing laboratory of the United States Geological Survey, which is now part of the laboratory of the Bureau of Standards, located in Pittsburg, Pa., and was placed in operation on September 12. At this time, a number of members of the International Association for Testing Materials were present to witness its operation, and among their performances, a square brick column twelve feet high and four feet on each side, was broken; a load of 6,580,000 pounds was required to complete this test. The machine is designed with a capacity for testing pieces up to 60 feet in length and the distance between tension screws, is 6 feet. These dimensions fit the machine for testing exceedingly large columns as well as slabs, and by placing an extension table on the lower platen, the largest beams may be broken.

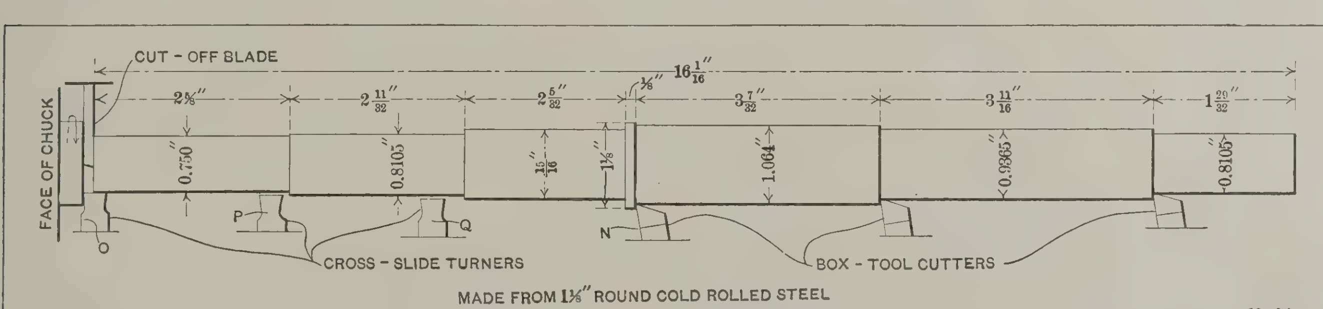

Fig. 2. Tools used in finishing the Shaft in One Operation

A SEMI-AUTOMATIC SLOTTING FIXTURE

BY J. H. HARRIS

The fixture to be described in this article is used by the Remington Typewriter Co. for the rapid and economical slotting of the part shown in Fig. 5. The fixture is semi-automatic in its action. It is carried on a shaft driven by the back-gears of a milling machine and all the operator has to do is to place the work between the jaws as they come around. As the fixture revolves, the work is fed against the cutter where it is slotted; it is then carried on to the discharge point and dropped into a pan provided for the purpose.

In starting to give a detailed description of this fixture, reference is first made to Fig. 1 where a plan view is shown. Here it will be seen that the fixture is carried on the horizontal driving shaft *A*. This shaft is supported at its outer end by the bracket *B*, which is clamped to the table by means of three cap-screws, and equipped with a bronze-bushed bearing *C* that carries the shaft.

A machine steel plate *D* is secured to the inner face of the bracket and two cams *E* are carried by this plate. Two elongated holes are cut in the bracket through which the cap-screws *F* are passed to secure the plate *D* to the bracket. These elongated holes give sufficient play to the screws so that the cams may be adjusted to exactly the required position. The arrangement of the bracket plate and cams is clearly shown in Fig. 2. The work is located in V-blocks *I*, against hardened steel buttons *J* that are carried by the casting *G* shown in detail in Fig. 3. This casting bears against the shoulder *H* on the driving shaft.

The clamping mechanism is carried by two castings *K* and *L*, which are doweled together and screwed to the casting *G*, as shown in Fig. 1. These three castings are secured to the driving shaft by means of the nut and washer *N* which force them against the shoulder *H*. The casting *K* is shown in detail in Fig. 6, where it will be seen that there are fourteen lugs in which the clamping members *P* are pivoted.

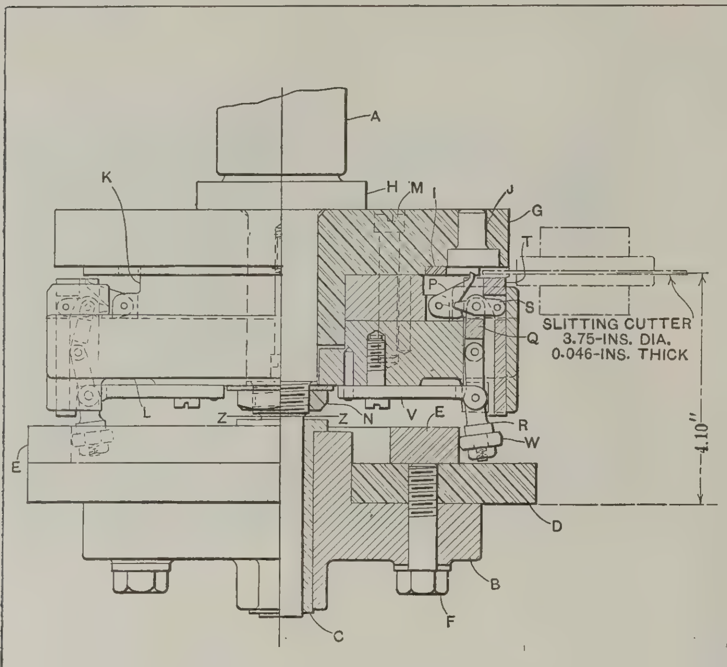

Fig. 1. Plan View of Slotting Attachment

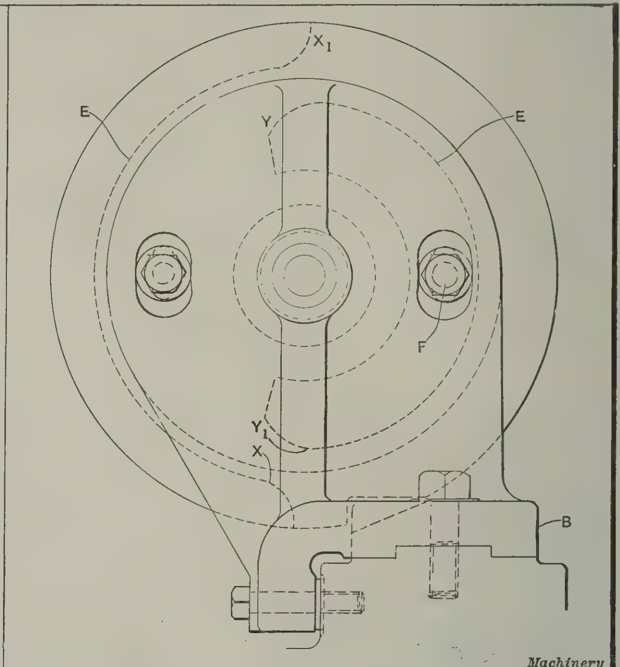

Fig. 2. End View, showing Arrangement of Cams and Bracket

Each clamp is operated by means of a pair of toggle jointed levers *R* and *Q* and a link *S*. As the link *S* is moved toward the back of the fixture it forces the sharp edge of the clamp *P* against the work. The opposite end of the link *S* engages with the clamp member *T* which slides in a hole in the casting *L*, as shown in Fig. 4. Each pair of clamping members *P* and *T* is thus forced simultaneously against the work by the action of the toggle levers, transmitted through the link *S*.

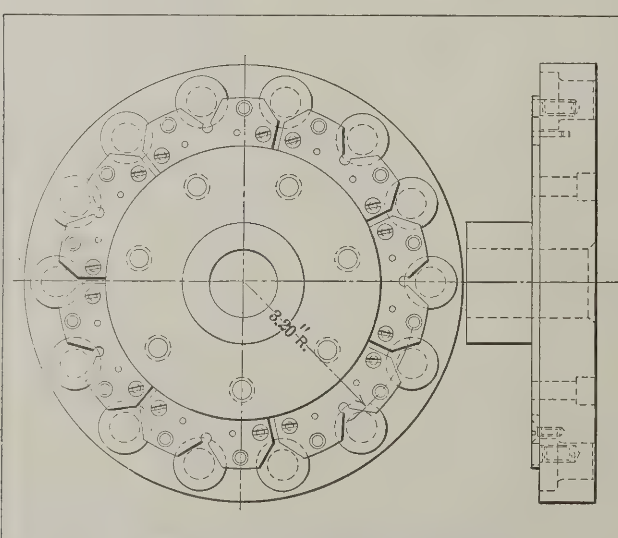

Fig. 3. Casting G, showing Method of Locating Work

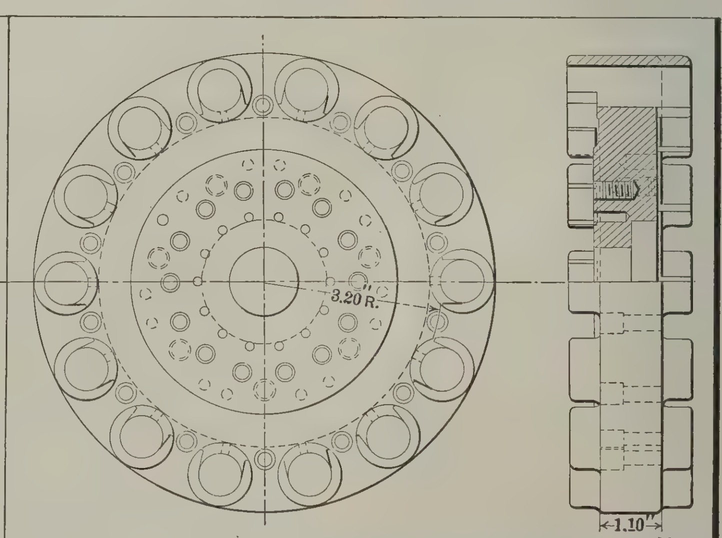

Fig. 4. Casting L, showing Holes for Clamps T

To explain the operation of the toggle levers, reference is made to Fig. 1, where one of the fourteen plates *V* that are screwed and doweled to the casting *L* is shown. These plates have a bearing at their outer ends in which the members *R* are pivoted. It will be apparent that any move- of the end of *R* will open or close the clamping members *P*

and T on the work through the pivoted connections between these members and S, Q and R. The required movement of the end of the levers R is secured through the action of the rollers W on the cams E. Referring to Fig. 2, it will be seen that the rollers at the ends of R bear against the inner sides of the cam plate at the left of the fixture from X to X_1. This holds the clamps open until the point Y is reached; from this point to Y_1, the roller bears against the outside edge of the cam on the right and between these two points the clamps are closed.

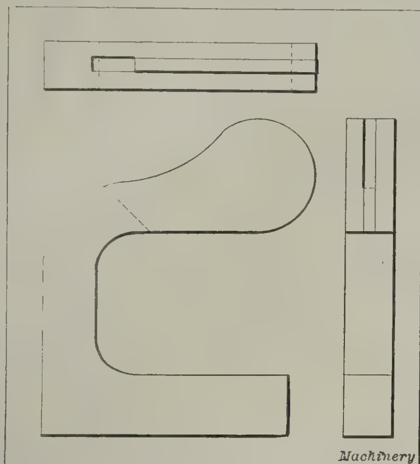

Fig. 5. Typewriter Part slotted as shown

It will be seen from this description that the work is placed in the fixture on the left hand side, where the clamps are open. It is then carried around to the right, where the clamps close before the work is fed to the cutter. The work is still held in the fixture until it has

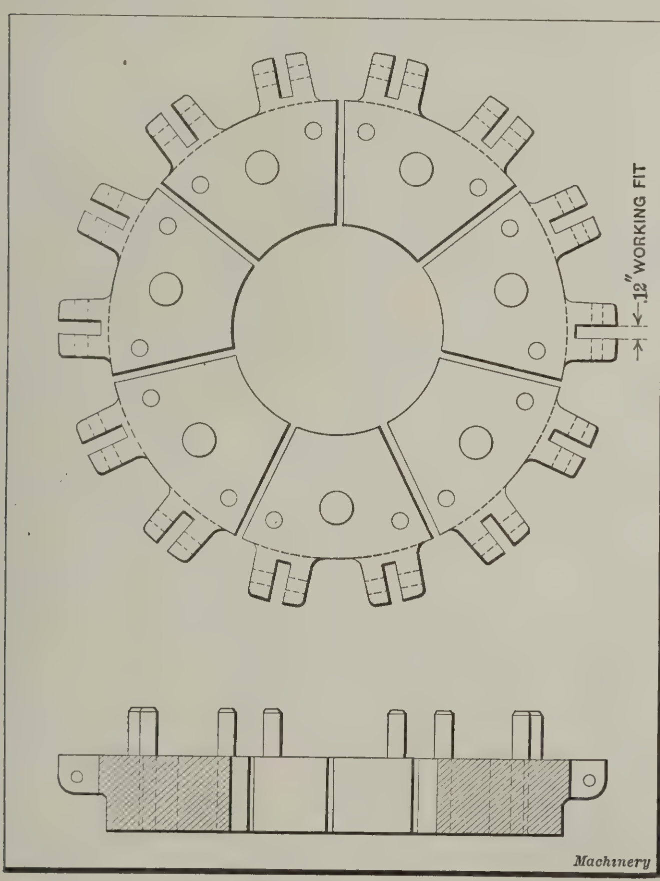

Fig. 6. Casting K, showing Method of pivoting Clamp P

reached the point X. Here each successive clamp opens and drops its work into a pan conveniently placed for the purpose. As the operation of the fixture is continuous, it enables the work to be rapidly handled at a consequently low cost.

* * *

Some interesting data is given in *Teknisk Tidskrift*, from a German source, of the large hydro-electric development at present being planned at Lyons, France. A dam is to be built across the Rhone which will produce a head of about 225 feet. The average amount of power that can be developed throughout the year is 350,000 horsepower. Present calculations indicate that it will be possible to deliver power from this development at the price of slightly less than one cent per kilowatt hour. It is planned to distribute the power over an area having a radius of between two and three hundred miles.

A PATENT OFFICE PARADOX

BY ROBERT MILLER*

Much has been published recently about proposed changes in the patent laws of this country. Numerous statesmen have drafted bills to remedy the evils that have been apparent for years. All this proposed legislation deals, however, only with the scope of the patent, and not one single sentence attempts to correct the one crying abuse of the entire system—interference.

When an inventor has his first dealings with the patent law he imagines that, except for whatever may be revealed by a search, and patent office citations against his application, he is fairly secure in his possession of protection for that which his brain has conceived. Yet, should an interference be declared, he awakes with a rude shock. It may be proper to first explain the term "interference." An interference is a proceeding instituted for the purpose of determining the question of priority of inventions, between two or more parties claiming substantially the same patentable invention. This sounds simple, but in its amplified form it can readily be made the means of the rankest injustice. For instance, A has a patent which has been issued for some time; if B files an application for the identical invention, an interference may be declared, provided B's application is filed within two years of the date of issue of A's patent. If the subject of the patent is a very valuable one and B happens to represent a powerful corporation, A, being a private individual, may be unable to fight for his rights.

The proceedings in an interference may be very costly, and are as follows: A notice of interference is sent to each party by the examiner of interferences; each party is then required to set forth, under oath, all of the details and circumstances, with dates, regarding the invention. These affidavits must be filed with the examiner before a certain date, and are termed preliminary statements. The examiner then appoints a time when testimony may be taken by each party to establish his position. During these proceedings an applicant or his attorney may cross-examine witnesses.

All this, of course, takes time, and, being legal procedure, also considerable money. Any patent attorney, therefore, would much rather handle a nice, complicated interference, than half a dozen ordinary applications. It might be possible, under the two-year clause, for a powerful interest to have an application filed after the issue of a patent, copying it, line for line and word for word, and by means of false witnesses prove priority, and thus have the original patent nullified and a new patent issued to itself. Further, the patent office itself, by its complicated rules, does not help to simplify the matter.

The writer will now describe an actual case, using some of the phraseology of the patent office. In this case A applied for a patent on a device in March, 1910; except for a few trivial references cited against the application, it was a clear case, and the claims were allowed in May of the same year. Being in no hurry to have his patent issued, he allowed almost the legal six months to elapse before making his final payment of twenty dollars. The patent was issued in December, 1910. The patent received considerable attention in the trade press, as the device was of a type just then of considerable interest to the industry.

In August of the following year A received notice of an interference with B. The usual preliminary statements were filed, and it was learned that B had filed his application in July, 1909, almost a year before A had. The drawings and specifications showed that both were identical in so far as the idea of the device was concerned. The claims were different, yet any novice could see that here were two applications lying together in the same class and sub-class, for a patent of the same device. Yet, the patent office did not declare an interference at this time, but waited until after the issue of the patent to A.

An industry might have been organized on the strength of A's patent, which would have prospered for a short time, and which would then either have been forced out of business, or been obliged to pay B large royalties—all this after having

* Address: 2136 La Fontaine Ave., New York.

obeyed the letter and spirit of the law, acceding to every requirement of the patent office and paying the just dues.

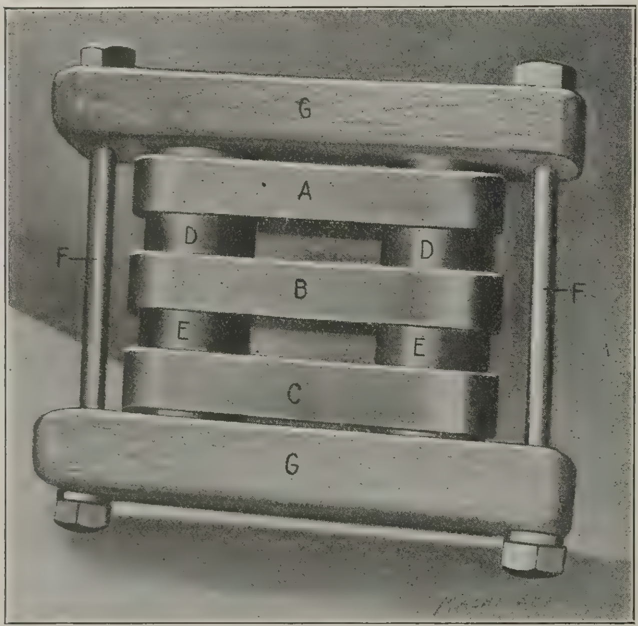
A direct appeal was made to the commissioner to explain this peculiar occurrence, asking why the interference had not been declared before the issue of the patent. The reply was that as the claims were different, "it was not proper to suggest A's claims to B." A case was then cited to the commissioner in which the office had suggested claims to both parties for the purpose of causing an interference. The reply to this communication quoted some obscure rule that was supposed to fit the case. The patent was, of course, granted to B as it should have been in the first place. For this same patent, therefore, two complete fees were paid, and to the man in the street it would seem as if there ought to be a refund. To a lawyer this would seem to be a square deal—with about ten thousand interferences a year the profession should prosper; to the man trying to improve things, it is discouraging.

* * *

A BUILT-UP LIMIT GAGE

At the shops of the New Departure Mfg. Co., Bristol, Conn., a type of limit gage is used by the inspectors that has the advantage of being easily kept in good condition. The illustration represents the general appearance of the gage.

The openings in the gage are the spaces between plates *A* and *B* and *B* and *C*. The space between *A* and *B* is regulated by size blocks *DD;* in this particular instance the size blocks are 0.4999 inch. The opening between *B* and *C* in this gage is regulated by size blocks *EE* which are 0.5001 inch in thickness. The strips *A*, *B*, and *C* may be of any convenient thickness and, of course, they are hardened and



A Built-up Limit Gage

the gaging surfaces are ground and lapped. The important parts of the gage, parts which regulate its accuracy, are the size blocks *EE* and *DD*, which, of course, must first be very carefully ground and lapped to size. After the size blocks have been placed between the gaging strips, small disks are applied to the outside of the strips *A* and *C* and the entire built-up gage is clamped together by bolts *FF* which pass through wooden strips *GG*. The object of the wooden strips is to provide a means for handling, without affecting the accuracy of the gage by the heat of the hand.

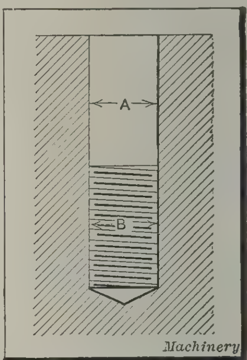
To maintain the accuracy of such gages it is only necessary from time to time to release the tension upon bolts *FF*, remove strips *A*, *B* and *C*, and regrind and relap the four gaging surfaces. It is not necessary to touch the size blocks as no wear comes upon their surfaces. C. L. L.

* * *

When cold-rolled stock is used, an allowance must be made in the bore, as this stock comes exactly to size or a trifle over size. When turned shafts are used, the bore should always be made standard, and the allowance made in the journal.

THE SCREW THREAD STANDARDS

Since a few years ago when the tap makers agreed to start a campaign against the sharp V-thread, the use of this form of thread has steadily diminished. Some of the tap makers, however, state that they still make as much as forty per cent of their taps with V-threads, while others make only from thirty down to ten per cent of their total production with this kind of thread, the remainder being the United States standard. An interesting reason given for the continued use of the V-thread by one of the largest machine tool building firms in the country, is that a V-thread tap permits the tapping of the bottom of a counterbored hole with the same diameter thread as the diameter of the counterbore. In the accompanying illustration the diameter of the counterbore *A* and of the thread *B* is nominally the same. When a sharp V-thread tap is used, of correct angle diameter, it will not be over the standard size on the outside diameter, on account of the small flat necessarily provided on the top of the threads. It can, therefore, enter the counterbored hole and tap the thread without scratching or marking the sides of the counterbored hole, which, in many cases, is required to be a good fit for the stud entering into it. If a U. S. standard thread tap were used, instead, the outside diameter of this tap would ordinarily have to be a certain amount over size, and hence, it would scratch or mar the counterbored portion of the hole when entering. To avoid this, most designers have been in the habit of making the counterbore larger in diameter than that of the threaded portion, but this, of course, necessitates a shoulder on the stud and a larger diameter of stock. It would seem, however, that the condition mentioned would be met with in machine design so seldom, comparatively speaking, that it should not be necessary to maintain two standard screw threads on this account. The committee appointed by the American Society of Mechanical Engineers to investigate into allowances and working limits for the U. S. standard thread, will probably take up this question and suggest some means of overcoming the difficulty even when a U. S. standard thread is used. It is not desirable to have the two thread forms continued side by side, especially since—as has been repeatedly pointed out in these columns—there is no accepted standard dimensions for the sharp V-thread, the different manufacturers making taps with this thread to different standards or gages.



A Condition where the Sharp V-thread has shown Advantages over the U. S. Standard Thread

There may be cases where the U. S. standard thread is not the best one for the purpose, but they are comparatively few. One is staybolt taps which are being more and more generally made with a Whitworth thread on account of the decreased tendency of the staybolts to break when this thread is used. On account of the unequal expansion of the side sheets, the staybolt is bent back and forth, and if there is a sharp corner at the bottom of the thread, as in the case of the U. S. standard or the V-thread, a crack is more liable to develop than when the bottom is rounded, as in the case of the Whitworth thread.

The A. S. M. E. standard for machine screws seems to gain ground rapidly. Some tap makers state that they make nearly all their machine screw taps according to this standard, while others still make from thirty to fifty per cent of the old V-thread standard. There is a tendency among the larger concerns to adopt the A. S. M. E. standard exclusively, while the smaller concerns, to whom the expense for new gages is more serious, still retain the old standards. It would be a great advantage to the tap and screw makers, as well as to the mechanical trade in general, if the old standards could be entirely eliminated. It would seem possible for the tap makers to agree to make the old standard thread only to order, and to charge a higher price for taps with this kind of thread so as to discourage the use of the V-thread on both the machine screw sizes and on larger dimensions of screws and taps.

DESIGNING A HOB FOR HOBBING SPUR GEARS*

DETERMINING THE THREAD SHAPE, NUMBER OF FLUTES, AND GENERAL DIMENSIONS

BY JOHN EDGAR†

A reader of MACHINERY has requested information regarding the design of a hob to cut spur gears. The gears to be cut are cast-iron, and have 120 teeth, 16 diametral pitch and 5/8 inch width of face. The pitch diameter, hence, is 7½ inches. The hole in the hob for the spindle is to be 1¼ inch in diameter with a ¼-square inch keyway, the hob to be run at high speed.

The first thing to be settled is the form and dimensions of the tooth or thread section of the hob. If the form is to be the standard shape for the involute system with a 14½-degree pressure angle, the dimensions of the hob tooth would be as

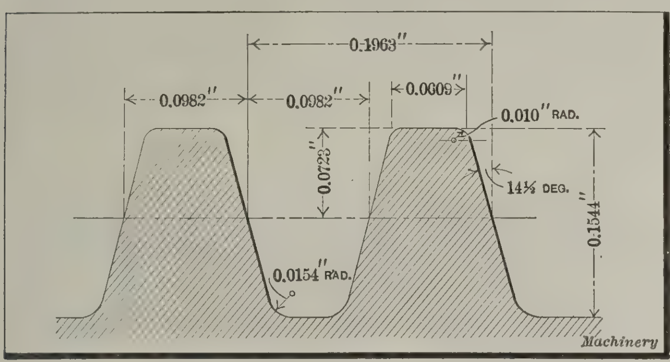


Fig. 1. Standard Hob Tooth Dimensions

shown in Fig. 1. A modification of this shape may in some cases be advisable, and will be referred to later in this article. The standard rack-tooth shape with straight sides, as shown in Fig. 1, however, is the easiest to produce, and unless gears with a very small number of teeth are to be cut, it is entirely satisfactory.

The circular pitch corresponding to 16 diametral pitch is 0.1963 inch which is obtained by dividing 3.1416 by 16. The thickness of the tooth on the pitch line is one-half of the circular pitch, or 0.0982. The height of the tooth above the pitch line is equal to the reciprocal of the diametral pitch plus the clearance, which latter is equal to 0.1 of the thickness at the pitch line. Hence, the height of the tooth above the pitch line equals 0.0625 + 0.0098 = 0.0723 inch. This distance equals the space in the gear below the pitch line.

The depth of the tooth of the hob below the pitch line is usually made greater than the distance from the pitch line to the top of the tooth. The extra depth should be equal to from one-half to one times the clearance. On small pitches, one times the clearance is not too great an allowance, and, therefore, the depth below the pitch line is made equal to 0.0723 + 0.0098 = 0.0821, making the whole depth of tooth equal to 0.1544. The extra depth at the root of the thread is to allow for a larger radius at the root, so as to prevent cracking in hardening. The radius may then be made equal to two times the clearance, if desired. In the illustration, however, the radius is made equal to 0.1 of the whole depth of the tooth. The top corner of the tooth is rounded off with a corner tool to a radius about equal to the clearance, or say 0.010 inch. This corner is rounded to avoid unsightly steps in the gear tooth flank near the root. Having obtained the hob tooth dimensions, the principal dimensions of the hob may be worked out with relation to the relief, the diameter of the hole and the size of the keyway.

The proper relief for the tooth is a matter generally decided by experience. We may say that, in general, it should be great enough to give plenty of clearance on the side of the tooth, and on hobs of 14½-degree pressure angle the peripheral relief is, roughly speaking, about four times that on the side. For cutting cast iron with a hob of the pitch in question, a peripheral relief of 0.120 inch will give satisfactory results; for steel, this clearance should be somewhat increased. The amount of relief depends, necessarily, also upon the diameter of the hob.

With a peripheral relief of 0.120 inch, the greatest depth of the tooth space in the hob must be 0.1544 + 0.120 = 0.2744. The gash will be made with a cutter or tool with a 20-degree included angle, 3/32 inch thick at the point, and so formed as to produce a gash with a half-circular section at the bottom. The depth of the gash should be 1/16 inch deeper than the greatest depth of the tooth space, or about 11/32 inch.

The radius of the hob blank should be equal to 5/8 + 1/8 + 11/32 + the thickness of the stock between the keyway and the bottom of the flute. If we use a 3-inch bar we can turn a hob blank 2¾ inches in diameter from this, which would allow sufficient stock to be turned from the outer portion of the bar to remove the decarbonized surface. If we make the blank 2¾ inches in diameter we have 9/32 inch of stock over the keyway, which is sufficient.

The number of gashes or flutes depends on many factors, some of which have been previously discussed in MACHINERY. (See the article "How Many Gashes Should a Hob Have?" in the January, 1909, number.) In Fig. 2 is shown an end view of a hob with twelve gashes. This number gives plenty of cutting teeth to form a smooth tooth surface on the gear without showing prominent tooth marks. A larger number of gashes will not, in practice, give a better tooth form, but simply increases the liability to inaccuracies due to the forming process and to distortion in hardening. This number of gashes also leaves plenty of stock in the teeth, thus insuring a long life to the hob.

The question whether the gashes should be parallel with the axis or normal to the thread helix is one that is not easily answered. It must be admitted that when the angle of the thread is great, the cutting action at both sides of the tooth is not equal in a hob with a straight gash; but in cases

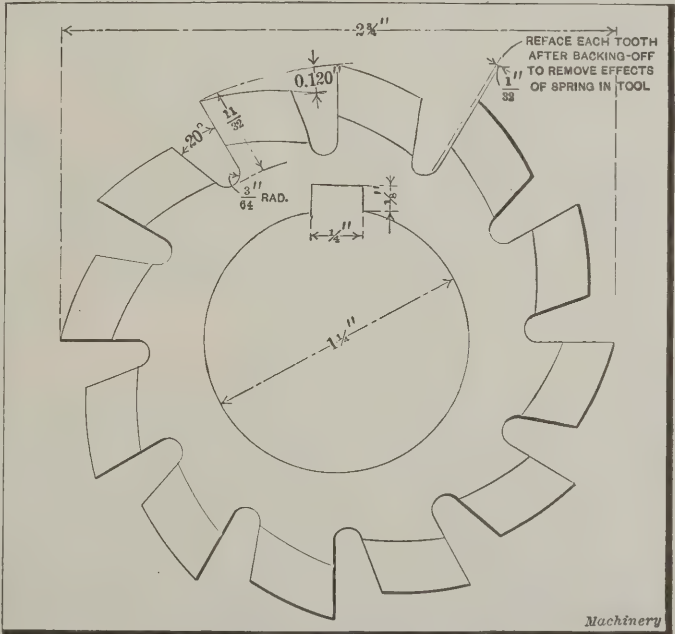

Fig. 2. Hob with Twelve Gashes or Flutes

of hobs for fine pitch gears, where the hobs are of comparatively large diameter, thus producing a small thread-angle, the parallel gash is more practical because it is much easier to sharpen the hobs, and the long lead necessary for spiral gashes, in such cases, is not easily obtained with the regular milling machine equipment. However, when it is desired to obtain the very best results from hobbing, especially in cutting steel, the gash should be spiral in all cases when the thread angle is over 2½ or 3 degrees. In our case the thread angle figured at the pitch diameter of the blank is equal to 1 degree 22 minutes; hence, straight flutes are not objectionable.

* See also MACHINERY, July, 1912, "Hobs for Spur and Spiral Gears," and the articles there referred to.

† Address: 61 Bruce Ave., Windsor, Ontario.

The linear pitch of the hob and the circular pitch of the gear, when considered in action, are to each other as 1 is to the cosine of the thread angle. In the present case they do not differ appreciably and may be considered as equal. In cases where the difference is over 0.0005, the true linear pitch should be used.

The change-gears for the lathe may be figured by the formula:

$$\frac{\text{Gear on lead-screw}}{\text{Gear on stud}} = \frac{\text{lead of lead-screw}}{\text{linear pitch of hob}}$$

On a lathe with a lead-screw of six threads per inch, or a lead of 1/6 or 0.1667 inch, the gears that would give accurate enough results for the present hob would be 28 teeth on the lead-screw, and 33 teeth on the stud.

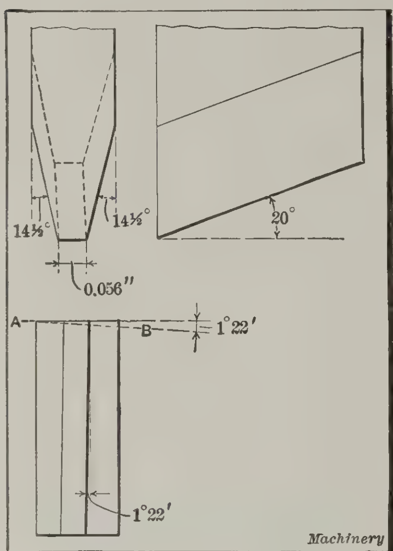

Fig. 3. Threading Tool for Hob

In Fig. 3 is shown the hob thread relieving tool. The front of the tool is relieved with a 20-degree rake for clearance. The sides are ground straight at a 14½-degree angle to form the sides of the thread, and are at an angle of 1 degree 22 minutes with the vertical to clear the sides of the thread. A tool made like this can be sharpened by grinding across the top without losing its size or form. If the gashes were made on the spiral, the top of the tool should be ground to the angle of the thread, as shown by the dotted line *AB*. In cases where the angle of the thread is considerable, the angle of the sides of the tool must be corrected to give the proper shape to the hob tooth. (See MACHINERY, May, 1905, or MACHINERY'S Reference Book No. 32, "Formula for Planing Thread Tools.") The point of the tool should be stoned to give the proper radius to the fillet in the bottom of the hob tooth space.

The best practice in making the hob is to anneal it after it has been bored, turned, gashed and threaded, the annealing taking place before relieving the teeth. Before hardening, the hob ought to be re-gashed or milled in the groove, removing about 1/32 inch of stock from the front side of the tooth to eliminate chatter marks and the effect due to the spring in the tool, which always leaves the front edge of the teeth without relief. In hardening, do not attempt to get the hob too hard, as the required high heat and quick cooling would distort the teeth badly.

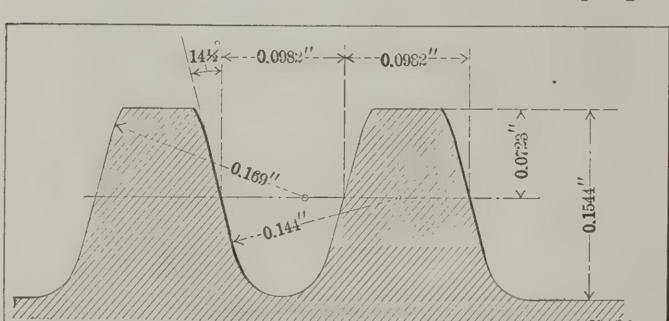

Fig. 4. Special Hob Tooth Dimensions

In case the 120-tooth gear is to run with a pinion of a small number of teeth and is the driver, as in small hand grinders where gears of this size are often used, it would be advisable to make the tooth shape as shown in Fig. 4. This shape will obviate undercutting in the pinion and relieve the points of the teeth in the gear so as to obtain a free-running combination. This shape is more difficult to produce and requires more care in forming. If the hob is made of high-speed steel, it should run at about 115 revolutions per minute for cutting an ordinary grade of cast iron with a feed of 1/16 inch per revolution of the blank. The feed may be increased considerably if the gear blank is well supported at the rim. The best combination of speeds and feeds in each case can be found only after considerable experimenting.

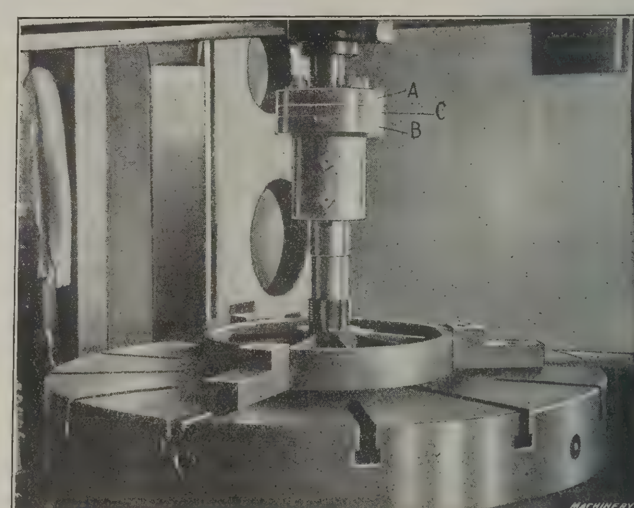
METHOD OF TAPPING FACEPLATES ACCURATELY IN A BORING MILL

At the New Haven Mfg. Co., New Haven, Conn., an interesting application of the familiar "Oldham" coupling is made use of in tapping the spindle holes of faceplates. Formerly considerable trouble was experienced when tapping faceplates, because if the work was not located exactly true with the boring machine spindle the tap would invariably cut large. By using the coupling shown in the illustration, trouble from this source has been overcome.

The upper half *A* of the coupling is held in the boring machine spindle and the lower half *B* supports the tap. Both these parts have on their inner faces shallow rectangular slots approximately ¼ inch deep by 1½ inch wide. The central part *C* of the coupling has on its upper face a tongue to fit the slot in the upper half and on its lower face a tongue is provided at right angles with the one on the upper face fitting in the slot in the lower half of the coupling. Four large cap-screws are provided which are threaded into the lower half of the coupling but pass through enlarged holes in the central and upper halves of the coupling. These screws serve merely to hold the parts together and do not prevent the parts of the coupling from adjusting themselves while the tapping operation is being performed. With this fixture the tap quickly finds a central location in the faceplate and the result is that the holes are quickly and accurately tapped.



Tapping Faceplates in a Boring Mill

C. L. L.

* * *

A Bureau of Mines paper states that all commercial explosives owe their power of doing work to the expansive force of the great volume of gas evolved from them at the moment of explosion. The pressure exerted by this gas in the drill hole or other confined space in which the explosion is brought about is what makes explosive substances of value in mining or other industries and is the primary cause of all those manifestations of energy that follow the firing of a charge. Common black blasting powder, on explosion, produces about 390 times its own volume of permanent gases: 40 per cent dynamite produces about 530 times its own volume of permanent gases; and nitroglycerin produces somewhat more than 747 times its own volume of permanent gases. These proportions of volume of gases to volume of explosive are those that would be found if the gases were measured under normal conditions of temperature and pressure, but at the moment of explosion the gases are highly heated, and therefore tend to occupy a volume much greater than the figures given above.

MOLDING DIES FOR FIBER INSULATION

BY EVERETT CHIPMAN*

The black fiber insulations shown in Fig. 1 are formed in molding dies which it is the purpose of this article to describe. The stock consists of fiber tubes which are made by rolling material of the thickness of paper on iron bars. During the rolling process, heat is applied in such a way that the material, which consists of pulp from wood fiber, is joined together to form a solid tube. The tubes are received in lengths of about 3 feet, and of varying diameters; they are sawed up into blanks of the right size for the different insulations and are then transferred to the forming presses.

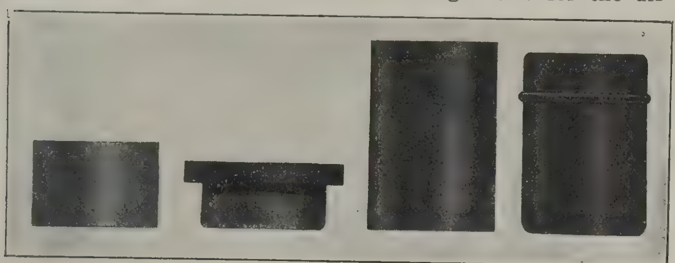


Fig. 1. Blanks and Fiber Insulations formed from them

Fig. 2 shows the punch and die used for molding the insulation shown at the left-hand side in Fig. 1. In this operation the shoulder is formed at the top and the lower edge is rounded at the same time. During this forming process the pressure applied causes a certain amount of shortening to take place; consequently it is necessary to allow enough extra on the length of the blanks to make up for this compression. The blanks are fed into the die by hand.

Reference to Fig. 2 will make the design of the punch and die used for this operation readily understood. *A* is the mold or form in which the outside of the blank is shaped. *B* is the plunger which is fastened to the head block of the press. *C* is the stripper for the form *A; C* also acts as a locating plug and forms the radius on the lower end of the blank. The plunger *B* has a recess into which the central stud of *C* enters as the press descends. The work is then formed in the space left between the mold *A*, the punch *B* and the locating plug *C* on the stripper, after the stripper has been pressed down to its lowest position. When the forming operation is completed, the finished blank is ejected by the action of the springs under the stripper. The finished insulation is held on the central plug of the stripper when the plunger has reached the top of its stroke, and can be readily removed with a fork-shaped piece of metal which lifts it off by means of the shoulder. This mold is used in a press having a ½-inch stroke and the work is produced with a variance of only two or three thousandths of an inch.

Fig. 3 shows a rather more complicated punch and die which is used for forming the insulation shown at the right-hand side in Fig. 1. This die represents the result of about three months experimental work during which time a number of methods were tried out and discarded.

In forming this insulation both the upper and lower edges are rounded and a shoulder is formed on the side as shown. It was the method of forming this shoulder which constituted the difficult point in designing the punch and die. The following notation has been adopted in Fig. 3 for refering to the different parts of the punch and die. *A* is the mold; *B*, the stripper for the mold; *C*, the punch; *D*, the stripper for the punch; and *E*, the central or locating plug. It will be noted that in this case the locating plug is carried by the punch stripper instead of by the mold stripper as in the preceding case.

The blanks formed in this mold fit into the recess in the die and rest on top of the stripper. The die is bored out to the outside size of the shoulder for a depth of about ⅜ of an inch, and there is an annular ring on the punch which comes down and fills the space between the outer wall of the blank and the outer diameter of the recess in the die. The lower edge of this ring is rounded and with the base of the counterbore in the die forms a semi-circular cavity in which the shoulder is formed. As the punch descends the central pin locates the blank and then enters the recess in the mold stripper which has been provided to receive it. The blank holds the two strippers apart against the tension of the springs until each stripper has reached its stop. The pressure is then increased, and since the only relief is in the ring at the point where the shoulder is formed, the fiber gives at this point and conforms to the desired shape. The punch and die stripper are of such a form that they round the corners at the top and bottom of the insulation as shown. During the return stroke of the press the strippers force the bushing to leave both the punch and die, and the finished work is left on the lower end of the locating pin, from which it can be readily removed.

During both of these forming operations there seems to be a slight movement between the layers of material in the blanks. The finished work, however, is perfectly compact, and if such a movement does take place it is probable that the heavy pressure of the forming operation generates sufficient heat to reunite the layers before the operation is completed. In each case the use of these dies has meant a great saving over the former method, which was the use of a molded paste composition for the smaller and screw machine work for the larger piece. The press method also produces more accurate work with less breakage.

WHAT IS SPACE?

In a paper on the fourth dimension, published in the *Polytechnic Engineer* for 1912, William J. Berry states that a serious difficulty presented in discussing mathematical subjects is the variety of meanings attached to words. A word may have one meaning to the physicist, another to the mathematician, and still another to the man in the street. "The average layman thinks of space, if indeed he thinks of it at all, as a huge box or hollow sphere in which all things lie—a sort of frame for the material universe. This idea is crude and vague. . . . . . Space is an idea caused by the perception of simultaneous groups of phenomena. Space is not a phenomenon or a group of phenomena, though without phenomena there can be no idea of space." The idea of space is subjective, and is distinguished in three forms, *i. e.*, visual space, tactual or feeling space and motor or traveled space.

ACTION OF PEENING STRAINS IN A CAST-IRON BENCH PLATE

BY DOUGLAS T. HAMILTON*

A cast-iron bench plate was recently brought to the Cleveland Machine Tool Co., Cleveland, Ohio, for machining, which was sprung out of shape, being 3/16 inch high in the center lengthwise and 1/8 inch high crosswise. This bench plate, which is shown in Figs. 1 and 2, is 7 feet long by 3 feet wide, the plate portion being 1½ inch thick before machining.

To straighten this plate, it was carefully clamped to the planer table, and a 3/16-inch cut taken over its entire surface. After taking this cut, a straightedge was placed on the plate which to the astonishment of the operator was found to be 3/16 inch low in the center. The supports under the center portion of the plate were held so tightly that they could not be moved, while the supports under the ends were loose. Another 3/16-inch cut was then taken and when the straightedge was applied, the plate was found to be 1/32 inch high in the center. A 1/32 inch cut was then taken, the straps released a slight amount and a final cut about 1/64 inch removed, which brought the surface of the plate back to a true plane.

Fig. 1. View of Bench-plate showing Triangular Ribbing

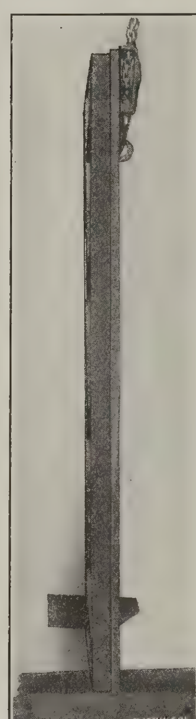

Fig. 2. Condition of the Plate after Machining

In clamping, particular care had been taken not to spring the plate, so that the action just mentioned cannot be due to that cause, and as is evident in the illustration Fig. 1, the plate was well ribbed and supported. The only conclusion which can be drawn from this peculiar action of springing, is that the plate had been used more in the center than at the ends, and that the surface had become stretched and hardened due to the continued peening action caused by hammering and placing work on it. Then when this hard scale was removed, the plate returned to its normal state—the fibers straightening out—this action being similar to that which takes place in a rod of cold-rolled steel, when only a portion of it is machined.

It is reasonable to assume that this same condition exists to a slight extent in a planer table which has been subjected to considerable use and abuse. The action of this plate also shows that extreme care is necessary in handling work on a planer table; it should not be used either as an anvil or a straightening plate, but simply as a means for holding the work while machining. Another point brought out by the action of this plate is that one cut cannot be relied upon to straighten a surface when it has become sprung. Some mechanics, when they get a job to do on the planer which must be accurate, put a broad tool in the holder and take a skin cut from the platen, thinking that by so doing they are producing a true plane. The fact of the matter is that in nine cases out of ten they have only partially relieved the strain and inaccuracy, especially if the planer has been in use for some time and has received rough usage. After taking a cut, the truth of the table should be proved with a dial test indicator held in the tool-holder, and it is generally advisable to take two cuts instead of one, that is, if the table is not sprung much, the dial test indicator being used to ascertain when the table has been brought back to a true plane.

THE INSPECTOR

BY JOHN F. WINCHESTER*

Writers in mechanical magazines often dwell on the importance of inspection systems and their relation to modern shop practice, but they seldom mention the qualifications necessary for a man to suitably fill the position of inspector, or the training that a man receives by occupying one of them. When it is considered that the keystone of success in many of our large manufacturing establishments is the inspection system, it can be seen that the human element should receive no small amount of consideration.

The requirements necessary for a man to fill satisfactorily the position of inspector vary with the concern for which he works and with the work to be done. In some factories there are inspectors who do nothing but measure duplicate parts; this particular branch of inspection can be filled by specialists with little training. In these same factories, however, there are inspectors who pass upon the final product. These men are held strictly responsible for the satisfactory operation of the product, and fill highly responsible positions.

Since the advent of the automobile, there has been a demand for another class of inspectors who are to pass upon all material that is to be used in the process of manufacture. These men test the material from the steel and iron mills and foundries, to ascertain if it meets with the required specifications. They are chemists or metallurgists, and generally have a college education or special training in that particular branch. This field is not closed to the shop-trained man, however, for with the correspondence schools, and with special courses in the engineering schools that now abound, it is within reach of him.

A man who had been promoted to an inspector was asked how he liked his new duties. He answered, "At its best, it is a thankless faultfinding position." This man did not possess the tact or proper ability to successfully fill his position and was mistaken in his estimate of it. It is not faultfinding when an inspector endeavors to detect the possible mistakes of others and report them to his superior, in order to prevent inferior goods from being produced.

The concern which employs the grades of inspector before mentioned usually has a chief inspector whose duty it is to oversee the inspection system and decide all important matters relating to it. This man must possess good mechanical training, have a decided, but not too aggressive, manner of passing on questions, and have an absolute knowledge of the details of the work being inspected.

The advantages of holding a position of inspector are numerous. He has a chance to learn by the mistakes of others, and meets with many perplexing problems, the solving of which gives him good training. He also enjoys the association of those higher up; associations count in any line of work, and the inspector, through being in contact with the executive heads of the establishment, is always in line for future promotion. Have we not here one of the ideal positions in a machine shop? I say "one of," for with the difference of opinion that always exists as to an ideal, I dare not put it stronger. It is one to which the apprentice with his boyish ambition may attain, and one which the elderly man who has held positions of greater responsibility, but with whom fortune has not dealt kindly, can accept and yet retain the dignity that he has acquired through his years of service.

EXPORT TRADE*

SOME OF THE CONDITIONS AFFECTING THE FOREIGN MACHINE TOOL BUSINESS

In no line of exports has the American spirit of ingenuity and invention proved itself greater than in the machine tool line. It is a field in which our conditions of labor made it especially necessary to invent machines to take the place of hand workmen. Following the Civil War there was a particular growth in machine design, and in 1876 the Centennial Exhibition at Philadelphia showed something of this new line of work. Up to this time a few of the manufacturers had been exporting in a quiet kind of way, had done a good deal of business, and had earned for American tools a reputation that was a desirable one. Greater developments in design came about, until seventeen years later at Chicago we had a magnificent showing of machinery that was instructive to ourselves as well as to the foreigners who came in great numbers. The best of the engineering ability not only visited the exhibition, but visited our shops and were received with open arms. Progress had been made in foreign countries, but not to the extent that was shown in America, and after the exhibition we had a very voluminous trade. Be it said to the honor of the machine tool builders that most of the material that went abroad was material that stood upon its merits and added to the reputation that our tools had already attained abroad. There were, unfortunately, some cases where unprincipled advantage was taken of the opportunity, but the great majority of the manufacturers seemed to appreciate the real value of the opportunity.

Since that time our foreign friends have no more stood still than have we, and in the reports obtained from those who visit the foreign market to study conditions we get confirmation of what we see with our own eyes when visiting these countries—that designs are constantly improving, and that the workmanship is approaching that which we furnish from this side. That we are copied to a greater or less extent may be sincere flattery, and while we can accept as a fact that a copy can be but second best, it is dangerous from a commercial standpoint for the reason that many are persuaded that it is as good; and the lower price that can be quoted by reason of the elimination of designing and experimental costs, to say nothing of difference in wages, adds to the difficulties in competition.

Neither our own nor any other country can or should have all of the business in machine tools. As our lines develop, there is no question but that one foreign country may excel another and ourselves in a given line of development, and when such a fact is realized, we should be as open-minded and as ready to purchase as we are to desire others to consider and purchase from us.

As a people we sometimes pride ourselves on our business spirit. So much have we talked about it that some of our foreign competitors have become so imbued with the fact that they call us not only aggressive, but egotistical, tricky and even brutal in competition. We admit we try to be aggressive, denying the remaining allegations as being too strong, but when we study the methods of some of our foreign competitors in working for export trade, we wonder if we are aggressive even, and our wonder increases as we compare foreign exports with our own. Are we inspired with the possibilities before us, and willing to add perspiration to inspiration?

Export business is no different from any other business in its principles. In our domestic trade there is no lathe nor milling machine tool builder who does not take such steps to sell his goods as will cause them to be purchased rather than the goods of a competing lathe or milling machine manufacturer. In such a case the manufacturer studies the market, and does what he considers is necessary to interest the prospective customer. In export business, instead of dealing with a neighbor who lives within a comparatively short distance of us, speaking the same language and living in the same general atmosphere of business and social conditions, we are dealing with customers who, except in the case of the English, speak another language, and all of whom live under conditions of life and are inheritors of business principles and methods that differ from ours.

What do we do to get domestic business? We try to get designs that are satisfactory and for which there is or can be secured a demand. We try to offer workmanship that is of a high order, and if we have competitors who have equally good designs and present equally good workmanship, we sometimes feel that by manufacturing more cheaply we can sell more cheaply, and thus obtain a market.

To sell goods abroad there are different courses open. The sales can be effected through agents who will act as representatives, through direct travelers, or through general agents who are but little more than commission merchants. There are representatives and representatives. If you sell through a representative that is thoroughly in sympathy with you, who will work for your interests, and who will represent you alone in your line, you are in a position to reciprocate and work for him. Such a representative must be taken into your confidence; you must listen to his requirements, and while it is by no means possible to grant all of the requests that he might make, it is possible to obtain from him suggestions that will help you in obtaining a share of the business that you are seeking. When selling through such a representative you are dealing with a concern that knows the people with whom it deals, knows their peculiarities, and can more readily make a trade than could a direct representative.

To think of sending a direct representative who cannot speak the language is so far from anything that any of us would do that it is hardly necessary to discuss this feature of the question; but given one who understands the language, he has to meet, as a direct representative, conditions that it is not easy for the home people to understand, so that it almost precludes this form of representation. When, however, you second the efforts of your representing agents with the services of a direct representative, results are oftentimes obtained that show that such services are an imperative necessity. This element is one that cannot call forth positive rules. If your machine is a type of special machinery, the need is far greater than when it is a type of standard machinery, and where to draw the line is a matter of opinion.

When goods are sold abroad through representatives, it is imperative that the house selling should have first-hand knowledge of conditions existing in their foreign trade. Your agents will write until they are black in the face, and get no response from you, when—did you but know a little of what they are contending with—one letter would have sufficed to place matters in order.

We all have something of an idea of what it means to have our literature in the language of the people that are to use the goods. Yet while we spend large amounts of money on our domestic business—on circulars and all kinds of printed material—we are apt to hesitate at printing in a foreign language when we are looking for the export business. This also brings up the matter of correspondence. Are we as apt to be as prompt in answering our foreign correspondents as we are our domestic friends, especially if the latter are not more than a hundred or two hundred miles away? Are we not a little apt to think, "Well, he has been waiting for ten days, a day or two more will make no difference," rather than to think, "He has been waiting for ten days, and how tedious it must be to have to wait another ten days; therefore this letter will be answered ahead of our New York letter." As a general rule do we watch the sailings of the mail ships as closely as the foreigner and attempt to make certain that given letters and documents reach New York in time to make the best connections?

Have not some of us felt the export business was a splendid thing in bad times, but a nuisance in good times? Have we not been rather apt to give, not a *just* delivery to our foreign friend, but to give him the delivery that was left over after our domestic friends were taken care of? When we are called upon

* Abstract of paper read by Mr. W. A. Viall of the Brown & Sharpe Mfg. Co., Providence, R. I., before the National Machine Tool Builders' Association Convention in New York City, October 16, 1912.

to put up some special form of packing to meet certain conditions, do we not feel that our representative is perhaps a little over particular, if not cranky, and make him feel that what is good enough for us is good enough for him, rather than to attempt to judiciously follow his wishes? Do we visit our representatives or have them visit us so often that we can talk over the things that are going on and become more closely allied? If we do, we are backing up our representative as thoroughly as we are backing our own salesman on our own ground, but if we do not we are merely playing with our foreign business.

The United States is not the only country that has customs' regulations. We find that foreigners take the utmost pains to conform to our American customs' requirements when exporting goods to this country; but when we export to their country, are we not rather apt to consider it more or less of a nuisance to carry out in detail the requirements of those countries, and work half-heartedly, with the result that the receiver of our goods abroad is put to such trouble that he will prefer to buy from the foreigner who meets him, rather than from the American who holds off?

In the case of the foreigner we find that he goes into neutral territory, and we are informed that he will give precedent to the foreign over the domestic business. While this may be hard on his domestic customer, yet there is a national feeling at times that makes him think that he can handle his home trade rather differently from his foreign trade, to the advantage of his home trade, on the theory that he is building up his nation. Our country has not been noted, in the machine tool business at least, as being willing to use foreign countries as dumping grounds of our manufactures in the way of prices, charging all of the overhead expense to the domestic trade, and figuring the prices of the export at flat labor cost without overhead charge, but this is a thing that we are meeting in competition with foreign countries.

Wages are an important element in cost, but they are not standing still abroad. There are those who want to see lower tariffs, which will mean lower cost of living and lower wages, and then perhaps there will be a competition that will be carried forward on a basis we have not yet been able to attain, and many of us hope we shall not attain.

We have one difficulty in getting into European markets that our European competitors do not have, in that we have a great distance to travel, and this oftentimes prevents our sending men, and lessens the number of visitors—conditions which do not prevail among European manufacturers. When the South American and the Far Eastern markets are considered, however, the Europeans have as far to go as we have.

Many of us are of English descent and have inherited some of the English traits. The matter of language is one of them. How often we hear the American saying that the English language is good enough for him and let the other fellow learn English. When we go abroad, however, we find everywhere people that are speaking English. Most of us are acquainted with the young men who come to America for the main purpose of learning English (and, incidentally, to learn some of our methods), and then in turn become the men who are doing business. A knowledge of foreign languages is not an absolute necessity for the export business, but it is certainly one of the advantages that those who possess it have. We would do well to consider whether it would not pay to send more of our young men over, if for nothing more than to acquire one or two of the languages of countries where we want to do business.

If we follow closely the publications of other countries, we find in some of them indications of a spirit of cooperation not always evident in our own country. One of the purposes of our association is to draw together manufacturers so that we can act as a whole, so that we can go forth as a body of American manufacturers rather than as individuals—and results have already appeared in this direction.

In the year 1911 the United States exported to Italy, in metal- and wood-working machinery, 1,000,000 kilograms, and to Germany 6,000,000 kilograms; in 1910 America exported machinery into Switzerland to the value of 500,000 francs and into Germany to the value of 4,000,000 francs; and in 1909 America exported into France machinery to the value of 45,000,000 francs and into Germany to the value of 110,000,000. Considering these figures, is it not time that we carried into effect as individuals, and, when necessary, as an association, that attention to the requirements and desires of the foreign customer that we are giving to our domestic customer every day? In view of the figures quoted, it goes without saying that we must constantly maintain the highest standard of design and workmanship. But beyond this, what is the matter with our American export trade? Are our goods not fitted to the foreign market, or are they not properly presented to the buyer, or are the prices too high?

* * *

MAKING HINDLEY WORM-GEARING AT THE BROOKLYN NAVY YARD

When a battleship is in action it is sometimes necessary to revolve the gun turrets very quickly in order to train the guns or locate them in the proper radial position. Owing to the weight of the guns and their inertia, the mechanism for revolving the turret must be very strong and powerful to withstand the sudden shocks incident to the rapid movements which are occasionally required. The turret rotating mechanism that is applied to battleships now being built in this country consists of two motors connected to a differential gearing from which power is transmitted to the turret through Hindley worm-gearing and a pinion engaging an annular rack attached to the turret base. When both motors are operating at what might be called the normal speed, the differential gearing and turret remain stationary, but by varying the speed of either motor the turret is caused to revolve, the direction of rotation being controlled by running one motor or the other faster than the normal speed. The Hindley worm-gearing is an important part of the turret controlling mechanism, at least from the shop man's viewpoint, because gearing of this type is rather difficult to make accurately, especially in the large sizes required for the purpose mentioned.

The accompanying illustrations, Figs. 1 and 2, show a simple method of producing these large gears, which is employed at the Brooklyn Navy Yard. An ordinary lathe equipped with a special attachment is used for machining both the worm and worm-wheel. Fig. 1 shows how the worm is threaded, and Fig. 2 illustrates the method of hobbing the worm-wheel teeth. The worm is made of steel and has a pitch diameter of 10 inches, whereas the wheel is made of phosphor-bronze, has a pitch diameter of nearly 36 inches, and a circular pitch of 3⅛ inches.

The worm blank, which is integral with its shaft, is first turned to the proper curvature in another lathe, as will be described later. When the worm is being threaded, the right-hand end of its shaft is supported by the tailstock center, and the left-hand end enters a special driving plate *G* (Fig. 1), which is bolted to the regular faceplate of the lathe. A shaft is keyed to this driver and carries a bevel gear *A*. This bevel gear meshes with a corresponding gear *B* attached to a shaft at right angles, which, through the spur gears *C* and *D* and worm-gearing contained in the special base *E*, transmits motion to the spindle *F*. In this way, the worm is caused to rotate in unison with spindle *F* and the tool-holding fixture *H* mounted on it.

The worm thread is formed by two separate operations and two sets of tools are used. The first set are roughing or stocking cutters, which simply form rough grooves, and these are followed by a set of finishing tools which give the threads the required shape. Fig. 1 shows the finishing cutters in the tool-holder and the roughing cutters are on the lathe bed at *J*. The cutting ends of the roughing tools vary in shape, some being square, whereas others are beveled more or less; in addition, there are right- and left-hand side tools on each side of the fixture. By having tools of different shape, some cut in one part of the groove and some in another, which facilitates the roughing operation. There are eighteen cutters in all, the number being equal to one-

half the number of teeth in the worm-wheel. The circular tool-holder is mounted on a cross-slide which is fed inward by handwheel K, the latter being connected with the cross-feed screw through worm-gearing, as shown.

After the thread grooves have been roughed out, the roughing cutters are replaced by eighteen finishing cutters. The tool-holder is so constructed that these tools can be accurately located each time they are placed in position. This holder consists of a circular casting H, having a raised inner ring fitted with set-screws against which the ends of the tools abut, and a circular ring for clamping the tools. The latter are located circumferentially by slots cut in the tool-holder, and radially by measuring the distance between the cutting ends and angle-plate L. In case radial adjustment is necessary, this is effected by the set-screws referred to. The tools are all numbered and there are corresponding numbers on the holder, so that each tool can always be located in the same position. The tops of the tools are, of course, in the same horizontal plane as the axis of the worm. When finishing, the tool-slide must be fed in very slowly, as each tool machines a large surface, thus making it necessary to take light cuts. The gears C and D are so proportioned that each tool, at the pitch circle, moves a distance equal to the circular pitch of the gearing, while the worm makes one revolution. Lubricant for the cutters is supplied by the tank seen above the worm. The collars on each side of the worm are integral with the shaft and engage thrust bearings when the worm-gearing is assembled.

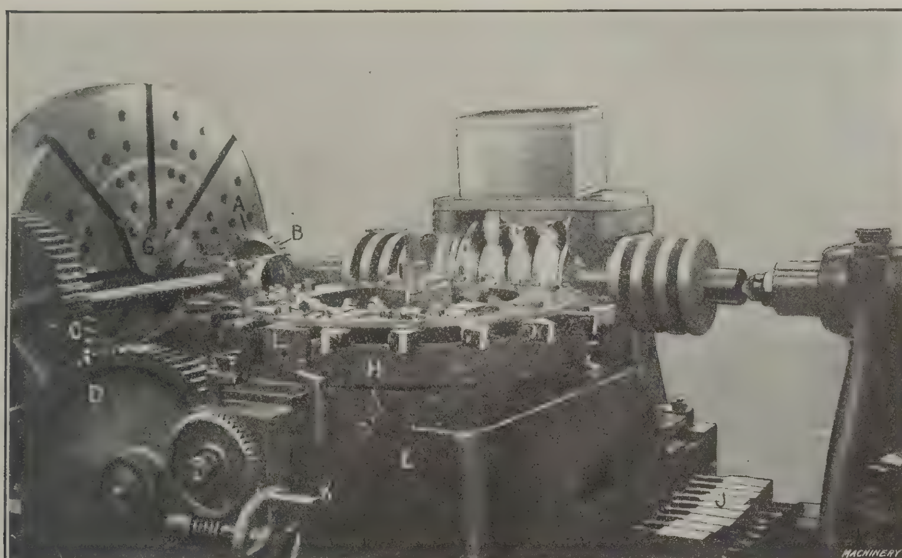

Fig. 1. Generating Thread of a Large Hindley Worm for the Battleship New York

When the worm-wheel is being hobbed (see Fig. 2), it is mounted on the same vertical spindle that drives the tool-holder, the latter being removed. The hob used for this operation has a long shaft which engages driving plate G, to which it is locked by a special key. The hob shaft also carries a bevel gear A for transmitting motion to spindle F through the shafting and gearing referred to. When hobbing the wheel it is necessary to run slowly and take light cuts, the same as when generating the worm thread, in order to secure smooth accurately finished teeth. The time required for hobbing one of these wheels is about five days, whereas the worm is threaded in about six days.

The hob used for the work, owing to its large size, was made with a machine-steel body, and the teeth are faced with tool-steel cutters K. These cutters are one-half inch thick and are held in position by cap-screws and dowel-pins. The inner end of each cutter is also fitted into a slot at the bottom of the gash, which gives additional support. When making the hob, the body was first turned and threaded just like a Hindley worm of corresponding size. Seven gashes were then sawed out to form the teeth, and the cutter-retaining grooves were milled. The annealed cutters or faces for the teeth were then bolted to the hob body, after being roughed to approximately the required form. The hob was then placed in the lathe and the tool-steel faces finished to the correct shape by hobbing with the worm-thread finishing tools, the operation being similar to that followed for making a worm. After hobbing, the sides of the cutters were filed to the proper degree of clearance. The clearance angle is about three degrees, although it varies somewhat owing to the change in the angle of the teeth due to the hob curvature. The final operation was that of hardening the cutters and attaching them to the hob body. By making the hob with a machine-steel body, the danger of distorting or cracking it by hardening was eliminated. There is also an advantage in having detachable cutters, in that they can easily be replaced if necessary.

The final operation on the worm-gearing is that of grinding the teeth to remove any uneven spots or ridges that may have been left by the machining operation. This grinding is done by running the worm and gear together and applying brick-dust and water, which abrades the threads of the worm and teeth of the wheel and produces smoother and better bearing surfaces.

The blank for the worm is turned in a lathe equipped with a special attachment which gives the required curvature. This attachment operates on the same principle as a regular taper turning attachment. It consists of a guiding templet having a curved slot, the radius of which corresponds to that of the worm. Engaging this slot there is a steel roller attached to a bar connecting with the lathe cross-slide, so that as the carriage feeds longitudinally, the turning tool follows an arc corresponding to that of the templet. This tool is centered with the blank longitudinally and is set in the same horizontal plane as the axis of the work. The phosphor-bronze blank for the wheel is turned to the proper curvature by means of a special attachment which consists of a tool mounted in a holder in such a way that it can be turned about a vertical axis, when finishing the curved periphery of the blank.

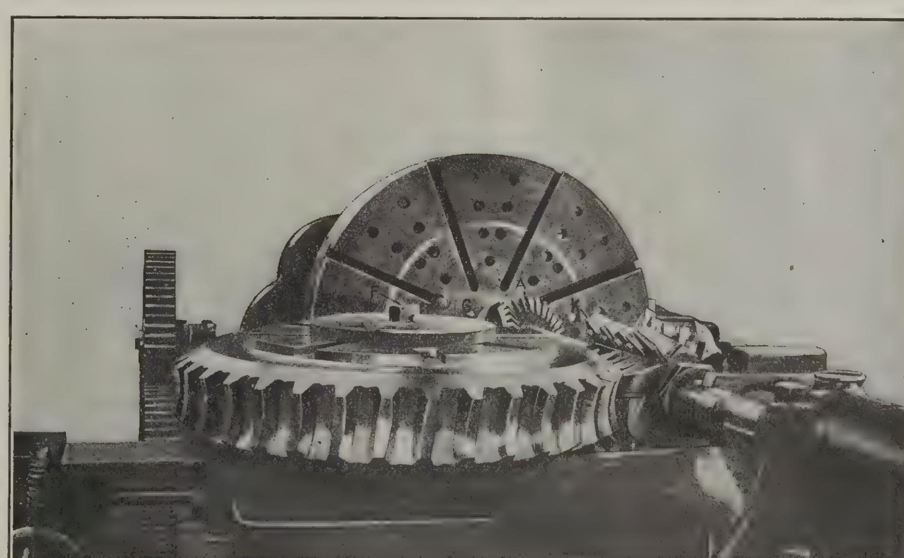

Fig. 2. Hobbing a Hindley Worm-wheel having a Pitch Diameter of approximately 36 Inches

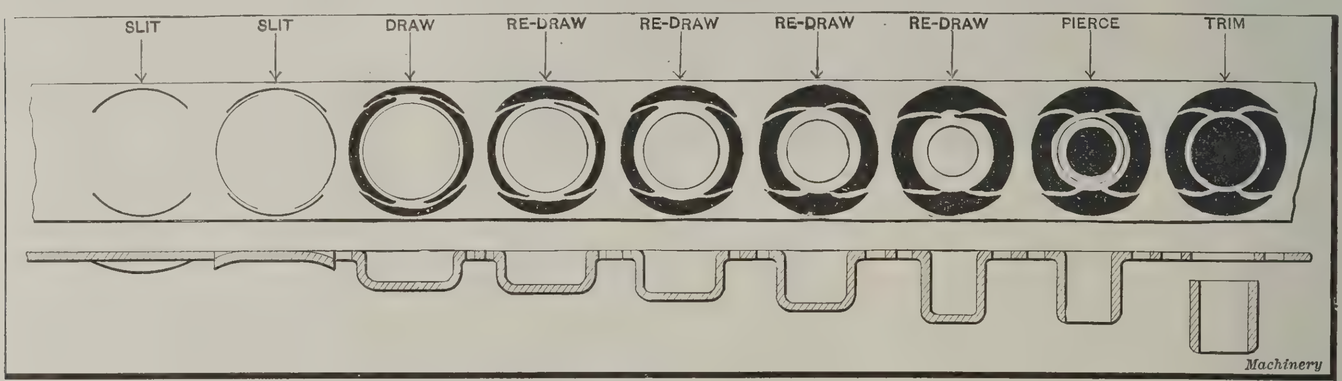
LETTERS ON PRACTICAL SUBJECTS

We pay only for articles published exclusively in MACHINERY.

PRODUCING DRAWN STEEL ROLLERS IN A GANG DIE

The illustration presented herewith shows the writer's idea of a layout for the progressive and automatic production of small chain rollers in quantities ranging from 18,000 to 22,000 parts per day per unit equipment. By using stock considerably thinner than the walls of the finished roller are to be, and working upon it progressively by means of gang or follow-up dies, as shown in the illustration, the roller can be completely finished in the power press. The plan view shows the entire evolution that the shell goes through to produce the result shown at the right-hand end of the sectional view. The stock used is dead soft, cold-rolled steel, which can be fed to the die by means of an automatic roll feed. At the first stroke of the press, the metal to form the shell blank is slit radially on two sides, as shown at the extreme left of the plan view. At the next stroke of the press, the metal is fed over one die space and is again slit. The next stroke performs the first drawing operation. The fourth operation is a redraw which is also the case in the fifth and sixth operations. The seventh operation is a finish-sizing process. In the eighth operation, the bottom of the drawn shell is punched out. The ninth and final operation consists of trimming the free end from the stock, as shown at the extreme right of the sectional view.



Evolution of a Drawn Steel Roller in a Gang Follow Die

At this point, the shells are annealed and then placed in a hopper. They are then fed to compression dies which apply end pressure to the tubes, and expand the shell walls to the required thickness. This operation will size and finish the rollers in exact duplication and to accurate dimensions. It will be seen from the layout that the work is carried along in the stock until the last operation, which cuts it free in the manner previously described. The writer estimates that the approximate cost of each unit die equipment, exclusive of a single acting power press, equipped with automatic feed, would be $300. A No. 19 single acting Bliss power press equipped with a No. 2 standard double roll Bliss automatic feed, is recommended as machine equipment. Stock ranging from 3/4 to 1 1/2 inch in width, and from 1/32 to 3/32 inch in thickness is best suited for producing such work.

New York City. J. V. WOODWORTH

THE TASK IDEA

The reader of technical literature today is likely to get the impression that the "task" system is a modern institution. This, however, is not so, for there exist today in England many concerns who have used this system for probably a hundred years or more. It is not quite the same system, however, for although the fixed task is there, no bonus is paid if it is performed in a briefer space of time than that set.

Fifty years ago, the writer's father worked under this system which was in vogue then and is still used in a large iron foundry employing about one thousand men. Pipes of all kinds are produced. Long experience has allowed the average time on a job to be accurately gaged, so that the output which constitutes a fair day's work is well known to everyone concerned. Disputes seldom arise and strikes are unknown. What is termed "80 inches" of standard socket pipe for gas or water is considered a day's work for a gang of men, but the number of men to a gang varies according to the size of the pipes. The unit "80 inches" means ten 8-inch pipes, eight 10-inch pipes, two 40-inch pipes, and so on. The gangs begin work at six o'clock in the morning and continue until the task per gang is finished and cast. Any bad castings have to be made good the following day.

The advantages of this system are manifold to the workmen, particularly in the smaller gangs where differences of opinion less frequently arise than in the larger gangs. When the whole gang is composed of fairly intelligent men, they can by steady work finish the day's task early, and enjoy long evenings for recreation and self-development. If a man wants an hour or two off, he only needs the consent of the other men in the gang. This has been agreed to by the management; all that is required is that the day's task is completed—there is no interference with the way it is done. By hard work a gang can finish at two o'clock in the afternoon, the furnaces and cupolas being kept going practically the whole day. Three or four o'clock in the afternoon are common hours for leaving. The wages earned are from 15 to 20 per cent greater than those of the ordinary day-workers who work until five o'clock.

The writer is not at all certain that present methods are an improvement on the old-fashioned way. Is it not a fact that the hours of labor at present are too long to permit of really efficient work during the whole of the day? Mind and body become weary, resulting in general inefficiency. But little time and, at any rate, but little inclination remains to devote the evenings to the study necessary to increase efficiency. Ten hours a day is too much for any man working at a monotonous occupation; eight is ample, and, in the opinion of the writer, would produce better results, if not in the immediate future, certainly eventually.

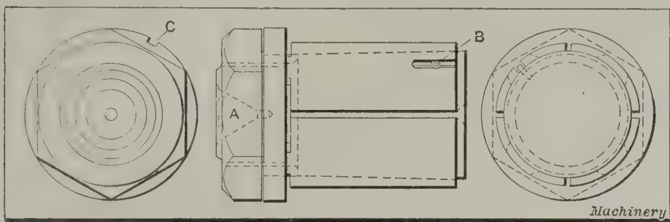
TIME LIMIT

EXPANDING CENTER FOR TURNING HOLLOW SHAFTING

A useful type of expanding center for use in turning hollow shafting, castings, or similar work, is shown in the illustration. It consists of a taper plug upon which a split shell is accurately fitted. In using this device, the lathe center fits into the hole *A*. The center is placed in the work and the split shell is then expanded through the action of the nut at the end of the plug. The pin *B* prevents relative rotation between the plug and shell, while the shell itself is held by a spanner fitting into the slot *C*. It will thus be evident that when the nut on the block is tightened, the shell is forced in on the taper and expands sufficiently to fit the work. When it is desired to disengage the block, the nut is slacked off. A sharp blow is struck on the end of the plug with a lead hammer. The center can then be as easily withdrawn as it was put into place.

These expanding centers have been found very useful on

many classes of work where the hole is too large to admit of the use of the regular lathe centers. They have been used in turning crankshaft parts, thrust, intermediate and tail-shafts for the steamship *Minnesotan*, the first of eight steamships now being built at the Maryland Steel Co.'s plant at



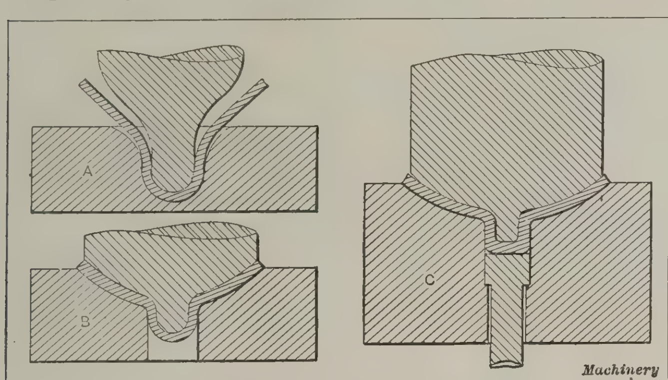
Expanding Center for Turning Hollow Shafting

Sparrows Point, for the American-Hawaiian Line. The work turned on this type of center is found to be as accurate and free from chatter as if the work were carried on the regular centers. LEWIS SYKES

Baltimore, Md.

DRAWING A SMALL SHELL FROM THICK BRASS

The shell shown in section in the dies at *C* in the illustration, is an unusually difficult job to draw from thick brass, the principal difficulty being due to the fact that the metal will not draw over anything approximating a sharp corner. The usual method of producing a shell of this kind—reducing it from larger cups by successive drawing operations—was tried without success. Finally the method shown in the illustration was hit upon, and it was found that satisfactory results could thus be obtained. This makes the operation akin to squeezing rather than drawing, the point being to protrude



The Three Dies used to produce the Shell

enough metal in the first and second operations to allow pressure from below to be applied in a third operation, shaping the stock and setting it to the required dimensions.

In the dies shown at *A* the object is to start the thick metal in a downward direction by means of the comparatively loose fitting punch and die shown. The edge of this die is very gradually rounded so that the metal will slide over easily. The second operation, which is performed in the dies at *B*, consists of shaping the shell around the depression already made, and the finished shape is the result of the operation performed in the dies at *C*.

The shell is started from a round blank, and two annealings are required to bring the metal to the finished shape. Subsequent piercing and cutting operations are afterward performed on the piece, but these do not differ from the general run of such operations.

Columbus, Ohio. OTTO R. WINTER

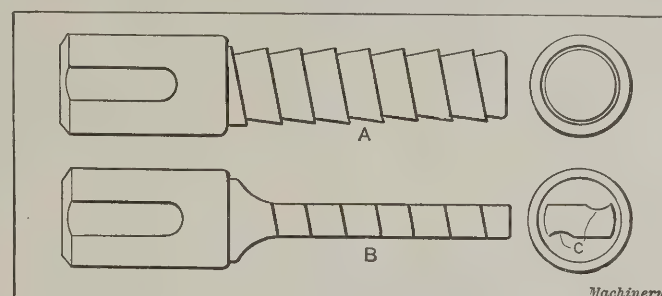
CHROME-VANADIUM STEEL FOR SCREW-DRIVERS

Screw-drivers made from properly heat-treated chrome-vanadium steel will be found superior to those made from other materials. Properly heat-treated chrome-vanadium steel possesses the hardness necessary to prevent the point from twisting off, and at the same time has enough toughness to prevent nicking or cracking; its torsional strength is exceptionally high. Actual tests have proved that when used for screw-drivers no material is superior to this steel. The heat-treatment should be as follows: Heat to from 1600 to 1650 degrees F., and quench in oil; then draw to from 700 to 800 degrees F.

Sandover, Md. W. A. SHERWIN

ROUGHING REAMER FOR CHROME-NICKEL STEEL GEAR BLANKS

Considerable trouble was met with in reaming tapered holes in certain chrome-nickel steel gear blanks. Several types of reamers were furnished by tool experts, but the results obtained were unsatisfactory. Finally, the type of roughing reamer shown in the accompanying illustration was devised. The blank for this roughing reamer was turned to the proper taper, but 0.005 inch smaller than the finishing reamer. A buttress thread of ½ inch lead was then cut on the reamer part, as shown at *A*, after which the blank was placed between



A Roughing Reamer used for reaming Holes in Chrome-nickel Steel

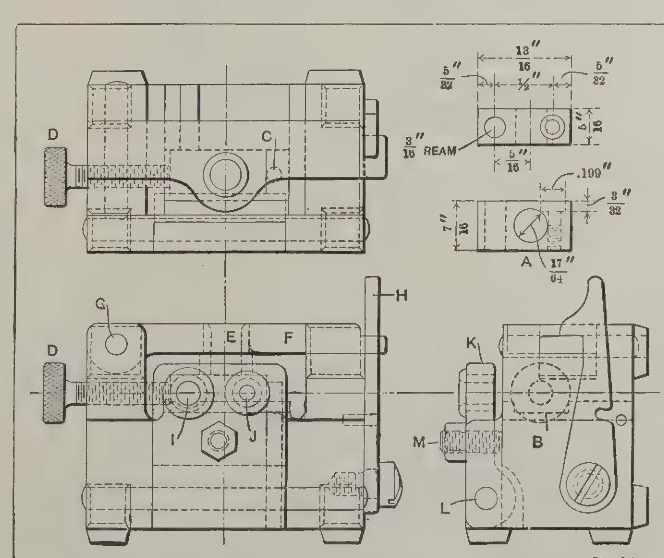
the centers in the milling machine and milled as shown at *B;* the cutting edges were then given the proper rake by milling two parallel grooves, as indicated at *C*. When removed from the milling machine, the reamer was finished by giving it the necessary relief on the cutting edges with a file.

This reamer was fed at a rate of 0.020 inch per revolution of the spindle, and after having reamed the hole with it, a finishing reamer of standard shape was used at slow speed, with a feed of 0.010 inch per revolution of the spindle. This reamer left a nicely finished hole.

Lafayette, Ind. W. H. ADDIS

DRILLING, REAMING, COUNTERBORING AND TAPPING JIG

A simple but very efficient jig for drilling, reaming, counterboring and tapping a part for a typewriter is illustrated herewith. The work shown at *A* in this illustration is a small



Jig for drilling, reaming, counterboring and tapping Piece A

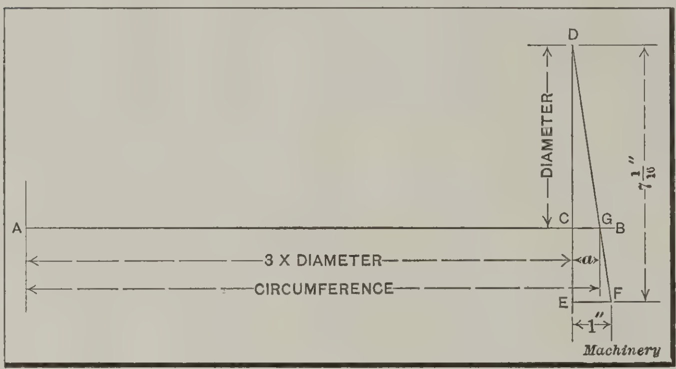
machine-steel block. This block is laid in a groove *B* in the body of the jig and is held against the locating pin *C* by means of the set-screw *D*. The work is held down by the head of the bushing *E* which is carried by the leaf *F*. This leaf swings

on a pin *G* and is clamped shut by the latch *H*. The largest hole is drilled through the bushing *E*, while the other two holes are drilled through the bushings *I* and *J*, which are carried in the second leaf *K* at the side of the jig. This second leaf swings on a pin *L*, but is not clamped shut. When closed, the adjusting screw *M* keeps the leaf in the correct position. After the three holes are drilled, the side leaf is lifted and one hole is reamed and the other counterbored and tapped. No guide bushing is used for the latter operation.

A. M. Rochester

LAYING OUT THE CIRCUMFERENCE OF A CIRCLE

The accompanying illustration shows a method by means of which the circumference of a circle can be laid out along a straight line, simply by using a scale. The method gives very accurate results. Lay out on line *AB* the distance *AC* equal to three times the diameter of the circle. At *C* erect



Method of Laying Out the Circumference of a Circle along a Straight Line

a perpendicular *CD* equal to the diameter of the circle; extend *DC* to *E* (if necessary), so that *DE* equals 7 1/16 inches. Draw *EF* perpendicular to *DE*, making it 1 inch long; draw *DF*, intersecting *AB* at *G*. (Should point *F* be located on the upper side of the line *AB*, extend *DF* until it intersects *AB* at *G*.) Line *AG* then represents the circumference of the circle.

Since the triangles *CDG* and *DEF* are similar, we have:

$$1 : 7\,1/16 = a : \text{diameter}.$$

Hence $a = (1 \div 7\,1/16) \times \text{diameter} = 0.1415929$, and $AG = 3.1415929 \times \text{diameter}$. Since the circumference of a circle is equal to $3.1415926 \times \text{diameter}$, this method is, theoretically, almost exact, the error being too small to be taken into account for any practical purposes.

Schenectady, N. Y.

THE VALUE OF AN EFFICIENT TRUCKING SYSTEM

It is surprising to note how little attention is paid to the method of handling work in some factories. These are generally the establishments which complain most of the heavy item which overhead expense makes in their cost of production. The argument is advanced that trucking is non-productive labor, and consequently does not need so much attention. This statement, however, is far from accurate.

In a certain large factory engaged in the manufacture of sheet metal products, the method of transferring work from shop to shop was seriously neglected. It was the practice to allow the machine operators to move their own work from department to department. Sheets of metal were loaded on trucks to carry them from one machine to the other, the trucks being unloaded before each operation was started. It will be evident that this method was responsible for a serious loss of time, and when this fact was recognized the mistake was corrected by adding fifty new trucks to the shop's equipment. These trucks were placed at the disposal of the men and orders were issued that all material should be kept on the trucks. This meant that each machine had two trucks; one to take away finished work and the other loaded with raw material. It may seem that the presence of so many large trucks would take up too much floor space, but the results do not show that this was the case, as the room occupied by the trucks was formerly taken up by piles of material and finished product.

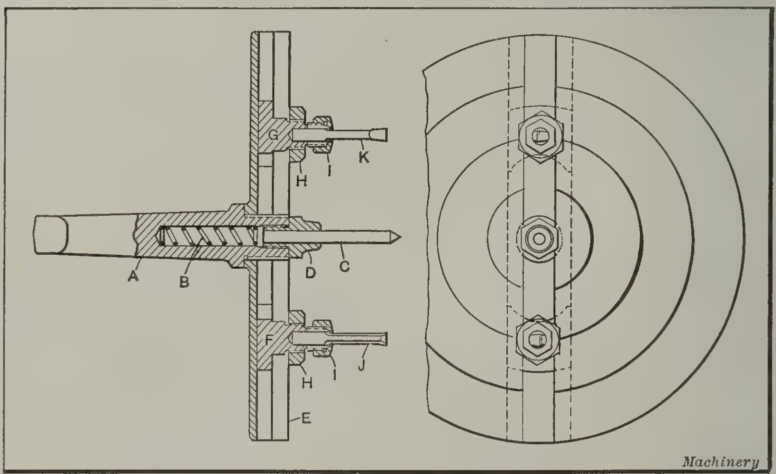
An important point in the development of the new trucking system was the maintenance of an aisle in each room, wide enough for two trucks to pass. The machines were arranged in progressive order on each side of the aisle, the men being required to keep the aisle-space clear. Instead of having the machine operators do their own trucking, a corps of truckers was employed under the direction of a floor manager, whose duty it was to keep the materials constantly moving from machine to machine as the various operations were completed. This floor manager ordered his raw materials from the yards and moved the work along through the departments as rapidly as possible. This kept each machine running continually and reduced the overhead cost to a great extent, owing to reduction in the amount of time which the equipment was idle.

New Britain, Conn. J. M. Henry

TOOL FOR CUTTING OUT RINGS OR DISKS FROM FIBER SHEETS

The tool shown in the accompanying illustration was designed for cutting out fiber rings or disks from the sheet, forming both the hole and the outside diameter in one operation; when desired, it can be used for cutting out the blanks only. The shank *A* of the tool is supplied with a Morse taper to suit a drilling machine spindle, and a hole is drilled in its lower end to receive the spiral spring *B* and plunger *C*, the lower end of the latter being cone-pointed. The top end of the plunger is provided with a head which acts as a stop for the plunger, coming against the threaded bush *D* screwed into the lower end of the shank *A*; this bush also acts as a guide for the plunger.

A disk *E* (which in this case is 5 inches in diameter) is screwed onto the lower end of the shank, and has a T-slot milled across its face to retain the tool-holders. The tool-holders *F* and *G* are made from a square bar, bored to receive a piece of round tool steel. The outsides of the tool-holders are turned, threaded and fitted with nuts *H*, which hold them in position in the disk *E*, when set to the required radius. The lower ends of the tool-holders are turned,



An Adjustable Tool for Cutting out Rings or Disks from Fiber Sheets

threaded, tapered and split, and are fitted with nuts *I* forming a split chuck for holding the cutting tools *J* and *K*. These tools *J* and *K* may be made in various lengths to suit the thickness of fiber to be cut.

The lower face of the disk *E* is provided with circles of various diameters and is marked so that the tool-holders may be readily set to cut any given diameter. The plunger *C* is so arranged that when pressed out by the spiral spring *B* to its extreme length, the point of the center projects about ⅛ inch in advance of the cutting edges of the tools. In using this tool, the fiber is marked with a center punch, the punch mark being located far enough from the edges of the sheet so that the cutters will not break out. The tool is placed in the spindle of a drilling machine and rotated at a good speed

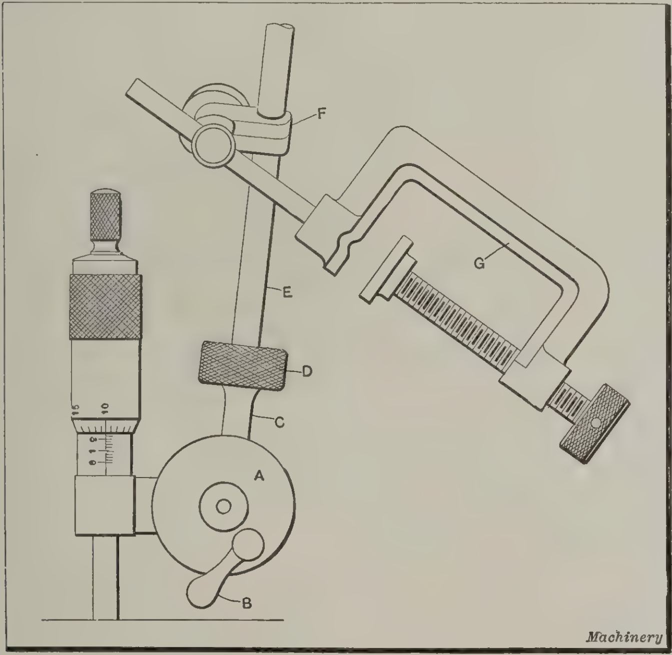
(say 1000 R. P. M.), the fiber being placed on the table of the machine with a thin board beneath it to protect the cutters when they pass the sheet. As the cutters are brought down toward the fiber, the center *C* which projects a little in advance of the cutters, comes into contact with the work first; this enables the fiber to be moved into the correct position, before the tools commence to cut, without stopping the machine.

When rings are required to be cut out, the inside cutter, or the one which is cutting out the hole is adjusted to cut the blank out of the ring before the other cutter separates the ring from the sheet; this insures the clean cutting out of the bore, and prevents the ring from being carried around by the cutter which is cutting the bore. The spiral spring behind the center, being stiff, holds the portion which is cut out first quite firmly in position, while the ring is being separated from the sheet. When cutting out blanks one of the cutters is removed. LAWRENCE W. WILLIAMS

Handsworth, Birmingham, England.

UNIVERSAL MICROMETER DEVICE

The writer has long felt the need of a micrometer device which would make it possible to remove surfaced work from the shaper, planer or milling machine and to replace it accurately. For this purpose, the tool illustrated in the accompanying engraving was devised. A standard 1-inch micrometer is used with the anvil part of the frame removed.



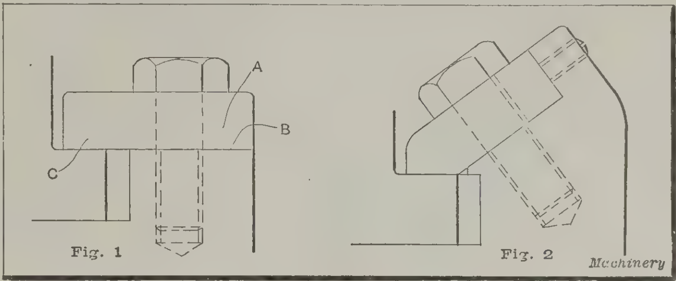
Universal Micrometer Head

The friction disk bearing *A* is mounted onto what remains of the frame, at right angles with the micrometer spindle. This bearing can be locked by handle *B*. Stud *C* is inserted in the disk bearing *A*; this stud is threaded to fit nut *D*. The support *E* is provided with a collar at one end that fits into nut *D*, this arrangement making it possible to use different types of supports. The purpose of nut *F* and clamp *G* is apparent from the illustration. The device can be clamped to any stationary part of the machine, and as it is universal in its adjustment and the micrometer spindle has a range of one inch, it is a very valuable tool for the machinist and toolmaker. WM. H. ADDIS

La Fayette, Ind.

DESIGN OF SQUARE GUIDE FOR SLIDES

Undoubtedly the square slide is to be preferred to the V-guide when friction and wearing qualities are considered, but the objection to its wider adoption is the difficulty of adjustment of the strip *A* in Fig. 1. On some slides where the wear is small this defect is not of much consequence, but on slides such as used for shaper rams, where the wear is great, the design presents a great drawback. In addition, the cost of fitting and adjusting the slide on a new machine, if a good fit is required, is objectionable. The only way of adjusting the strip is by carefully removing metal from the surface *B* until the required fit is reached. This lack of adjustability is also a bad feature when the machine has become worn through use. Because of the trouble involved in adjusting the strip, the machine is frequently allowed to run until it is in very bad shape.

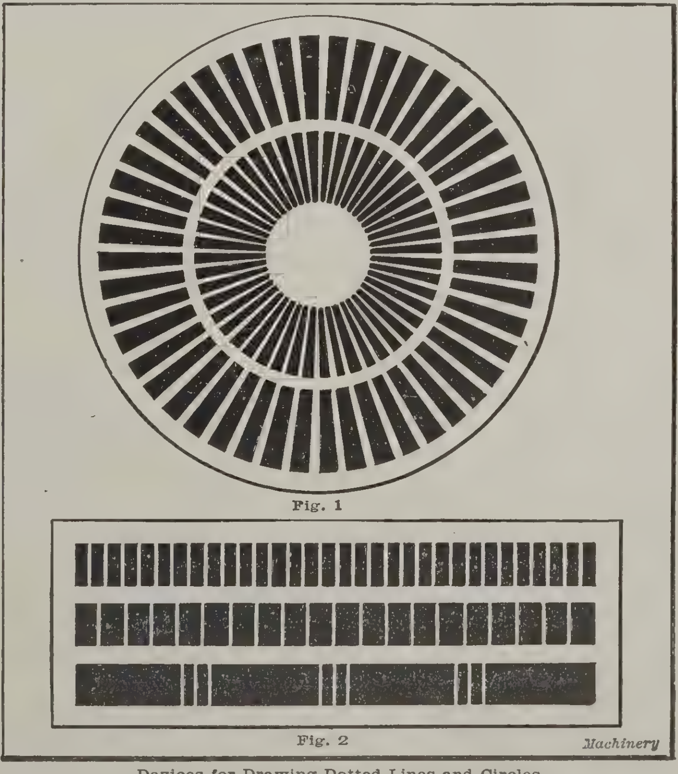


Figs. 1 and 2. Conventional and Improved Designs of Square Guide for Slides

The arrangement shown in Fig. 2 was intended to overcome the weak points of the design shown in Fig. 1, while still retaining all the good points. The construction can be quite massive, and as the bolt heads are practically over the heads of the thrust, there is little chance for looseness of the fit. The adjustment is very simple, and the ease of fitting is apparent. A. H.

DEVICE FOR DRAWING DOTTED LINES

The accompanying illustration shows the principles of a device for drawing dotted lines. It is well known that it requires considerably more time to trace dotted lines than to draw full lines and circles. The devices illustrated are made from thin sheets of amber or celluloid. The parts shown in black are cut out so that the pen will touch the paper at these points. The length of the dots and dashes can be regulated by the spacing of these sections. When drawing a dotted line, the T-square or triangle is simply placed over the "dotter" (Fig. 2) and the line is drawn as if it were a full line, without lifting the pen. When drawing dotted circles by means of the device in Fig. 1, the "dotter" must lie perfectly flat on the drawing. Care must be taken in lifting the "dotter" from the drawing so that the ink will not blot.



Devices for Drawing Dotted Lines and Circles

McKees Rocks, Pa. AUGUST H. ANGER

[It would seem difficult with a device of this kind to prevent the ink from flowing along the edges of the celluloid

and also that it would be almost impossible to lift the disk from the paper without causing ink blots. The idea was tried in this office, however, and found to work fairly well.—EDITOR].

FILING MACHINE BRACKET

The accompanying halftone shows the application of a special holding-down bracket used on a filing machine made by the Simplex Mfg. Co., in order to increase the range of work that can be handled on the machine. The arm is shown in detail in the line engraving Fig. 2. It is supported from the column of the machine and held in position by a clamp hub, and is as universal in its adjustment as the holding-down clamps furnished with the machine. Two offset fingers are used for clamping purposes. The use of this bracket makes it possible to keep the table clear for any class of work. After the fingers are set to accommodate the thickness of the work at hand, no further adjustment is required. One of the two ordinary clamps is also shown on the table in Fig. 1, merely to illustrate its appearance and application.

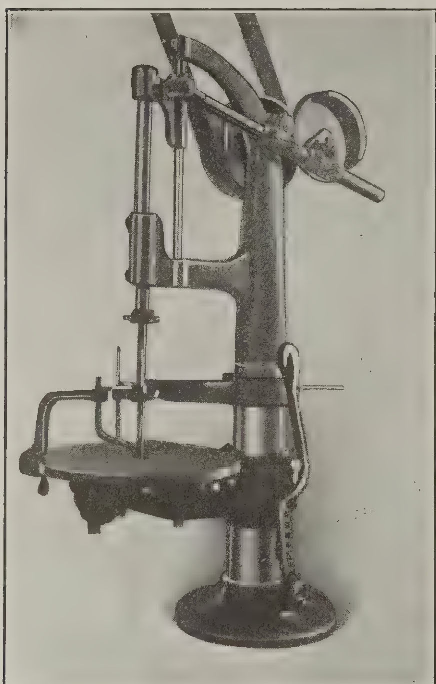


Fig. 1. Bracket applied to Filing Machine

The advantages of the bracket are particularly in evidence in cases where it is required, for example, to file a set of cams for a Brown & Sharpe automatic screw machine. The whole table of the filing machine would be unobstructed and any part of the cam could be filed without adjusting the holding-down clamps. On all kinds of dies and punches it is also especially useful for filing a circular portion. It is often desirable to be able to swing the work through a large arc, which this special bracket permits. D. SIGN

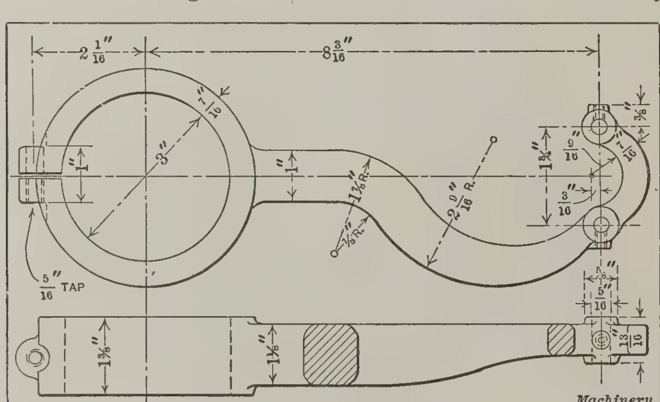

Fig. 2. Dimensions of Bracket

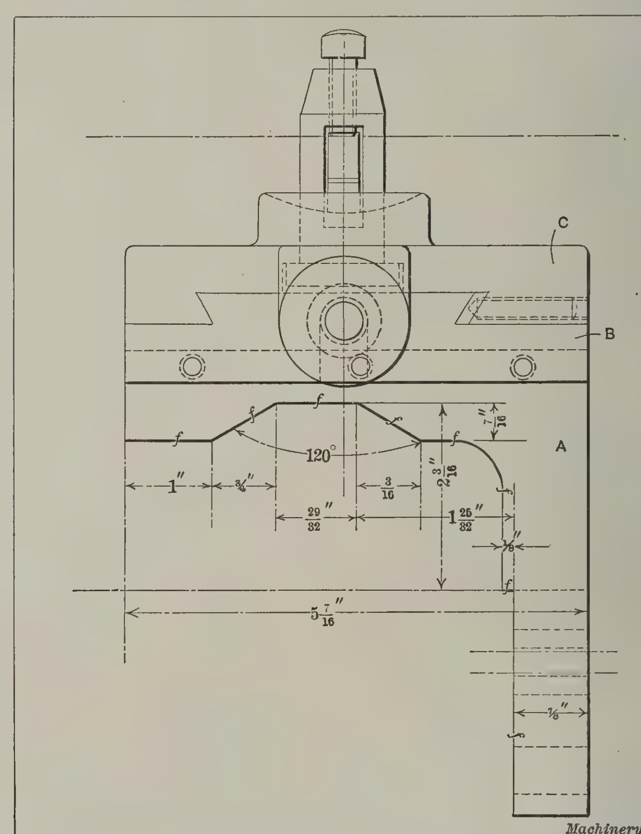
USING GASOLINE ON TRACING CLOTH

It is probably the most common practice in drafting-rooms to use powdered chalk or some similar preparation to absorb the greasy element on the surface of tracing cloth. While the results obtained are satisfactory so far as the object in view is concerned, the gritty preparation rubbed over the cloth will dull the finely sharpened edges of the ruling pen in a comparatively short time. For this reason it is preferable to rub the tracing cloth with a soft cloth slightly dampened with gasoline. When this practice is followed the ruling pen will be found to remain sharp much longer than when the tracing cloth is rubbed with chalk. Gasoline is also useful as an eraser for lead pencil marks and for cleaning a soiled tracing before removing it from the drawing-board.

Manchester, N. H. CLARENCE KENT

TOOL FOR FINISHING THREADS ON A THREAD MILLING MACHINE

The accompanying engraving shows a device used for finishing threads on a Pratt & Whitney thread milling machine. By means of this device objectionable milling cutter tooth marks can be removed whenever they become very apparent on the work, as, for example, when maximum feeds are used with such materials as cast iron, bronze and soft steel. The device consists of a bracket *A*, fitted to the carriage of the machine and bolted to the seat used for carrying the follow-rest on regular long work. The bracket bears on the top of the cutter-slide which is planed to an angle of 120 degrees. Mounted on this bracket is a slide *B*, parallel to the work.



Device for Finishing Threads on a Thread Milling Machine

This slide has provision for adjusting the finishing tool to the threads already roughed out by the milling cutter. This adjustment is accomplished by means of two fillister-head screws, one at each end of the slide. Attached to this slide is the top slide *C* in which the shaving or finishing tool is clamped. This latter is made from 3/8 by 3/8 inch stock, and is held in a regular toolpost. The top slide is operated by a small handle located immediately above the handwheel which operates the cutter-slide. This handle is provided with a graduated dial reading to 0.001 inch.

When this device is used, the milling cutter is fed into the work and the work roughed out to within from 0.002 to 0.004 inch of the finish size. The finishing tool is then brought into action, removing the remaining stock and leaving a smoother finish than could be obtained by milling alone with a heavy feed. J. E. SHEUMAN

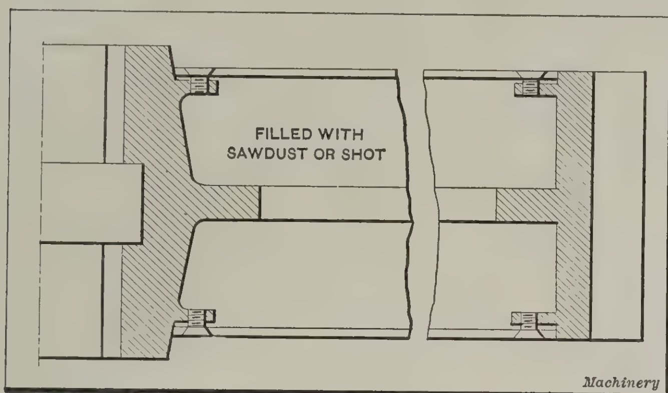
Waynesboro, Pa.

ANOTHER CURE FOR NOISY GEARING

In the May issue of MACHINERY, a cure for noisy gearing is mentioned which appears to combine the advantages of low cost and efficiency. The following method which is used

on a large scale in some engineering works in St. Petersburg, Russia, is even more efficient, but it is also far more expensive.

In using this method gears of less than 18 inches in diameter are fitted with two sheets of tin which enclose the space between the hub and the rim of the gear. This space is then filled with sawdust or with No. 4 shot, the idea being to eliminate vibration by this means. In some cases, it has been found advantageous to use a mixture of shot and sawdust. The sheets of tin are fastened to the rim and hub with a number of small screws, as shown in the illustration. When



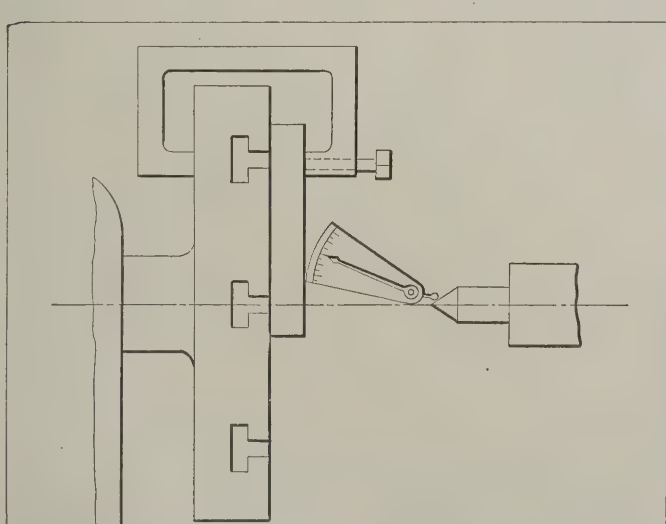
Method of Quieting Noisy Gears

the diameter of the gears exceeds 18 inches, wooden rings are used in place of the tin, the method of attachment being similar in either case. A felt packing is used to prevent the sawdust from leaking out. This arrangement has the further advantage of closing the space between the spokes of a wheel, thus making it impossible for a workman to get his arms or tools caught by the rotating wheel.

Wolverhampton, England. A. Wind

TESTING THE ALIGNMENT OF LATHE CENTERS

The writer once desired to know the alignment of the dead center of a lathe in which he had a piece of work mounted. This work was of an awkward shape, and after clamping it to the faceplate it was found necessary to bring the dead center forward to a hole which had been drilled, to assist in holding the work. When the lathe was started, a slight vibration of the center hole showed the center to be out of line with the lathe spindle. To bring the dead center into alignment,



Method of Testing the Alignment of Lathe Centers

a test indicator, graduated to read in thousandths, was clamped to the faceplate, in such a position as to enable the indicator point to come into contact with the end of the center. This is clearly shown in the illustration. When the lathe spindle is revolved under these conditions, the amount of error in the alignment of the dead center is accurately shown. This error can then be easily remedied.

This is a useful method of lining up centers before starting to turn a straight piece of work. It is far superior to the practice of taking trial cuts and making the necessary measurements and adjustments between cuts, in order to ascertain whether the piece will be straight when finished. Almost every tool-room has some kind of test indicator which is capable of being used for this purpose. F. E. C.

A STEADYREST NOVELTY

In the July issue of Machinery, E. W. Tate has a tilt at the steadyrest proposed by H. Terhune in a previous issue. He enumerates several rather visionary faults, and sets out to abolish them with a design which appears to me to perpetuate rather than remedy the very points he criticises in H. Terhune's design. And it was rather unfortunate, after complaining of the cost of the first design, when he confessed that the application of his own is limited on that account.

This controversy and the editor's trenchant footnote anent the neglect usually accorded these accessories has prompted me to advance a description of a type of steadyrest which is, as far as I know, quite novel, and which is both compact and cheap. This steadyrest can be made in two styles, as shown in Figs. 1 and 2, according to whether the screw is required to work the jaws both ways or not. The construction in

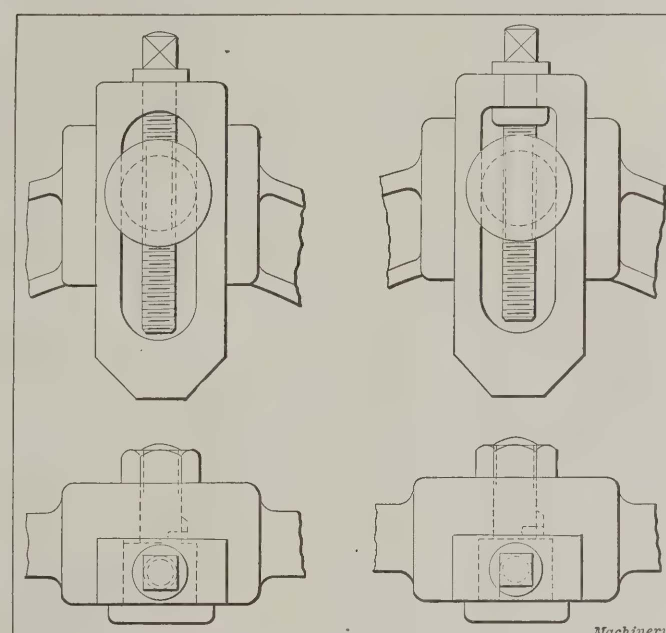


Fig. 1. Steadyrest to work Jaws in One Direction   Fig. 2. Steadyrest to work Jaws in Two Directions

each case is practically identical, the difference being that the type shown in Fig. 2 has the screw turned with a second collar, and the hole for the screw in the top of the jaw is milled out to the front. There are no unsightly screws projecting when the jaws are fully out, as in the case of many of the types now in use. The machining of the jaw guides can be done by an ordinary milling cutter going straight through, instead of end-milling them, which is now necessary with the blind end guides. A. H.

PUNCH AND DIE FOR FORMING ELECTRIC TERMINALS

The punch and die shown in Fig. 2 were designed for forming electric terminals of the type shown in Fig. 1. The arrangement has been so worked out that two terminals are formed and two others sheared off by each stroke of the press. The stock used is copper tubing, ¼ inch in diameter with a wall about 1/32 inch thick.

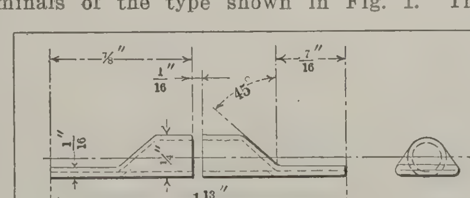

Fig. 1. Two Electric Terminals after being cut apart

Reference to the cross-sectional view of the punch and die

shown in Fig. 2 will enable the operation to be readily understood. In this illustration *A* is the punch which forms the work in the die *B*. The shear *C* is bolted to *A* and backed up by a shank to enable it to withstand the blow. The right-hand face of the die *B* acts as the lower shearing plate. *D* is a square block of tool steel which is used to straighten out the formed tube before the punch *A* descends for the next stroke upon the unformed section of the work. The use of this block has been found necessary to bring the flat portions of the double terminal into proper alignment. When the shear *C* is in the act of descending, distortion of the formed tube would be inevitable were it not for the action of block *D*.

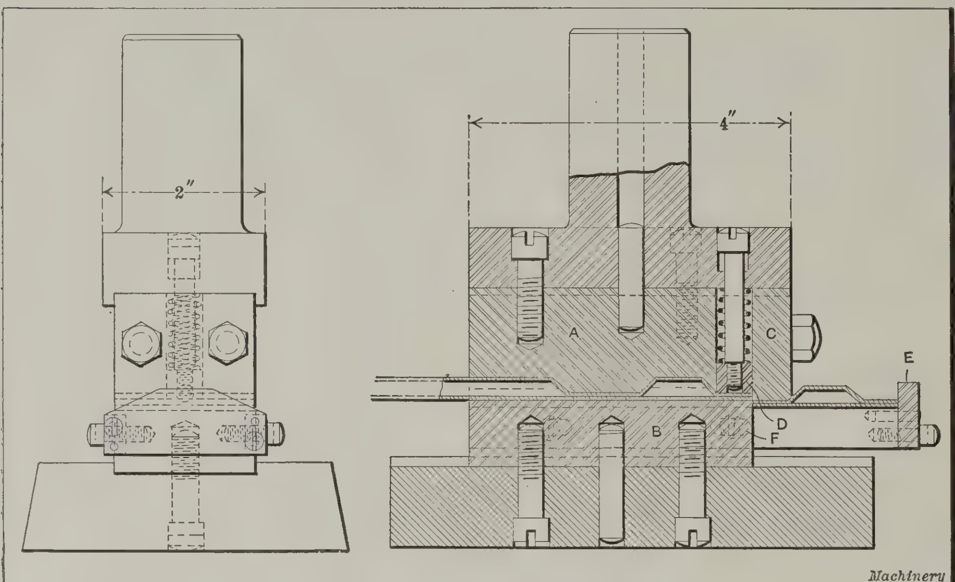

Fig. 2. Punch and Die for Forming Electric Terminals

The work is fed through the die until it comes up against the stop *E* which can be adjusted by means of screws *F* that are located in a suitable elongated hole. With the work in position against the stop *E*, the punch descends, shearing off the end of the stock and forming a double terminal between the punch and die. The work is now advanced to bring it into contact with the stop *E* and the punch is again tripped. This shears off the pair of terminals which were formed in the preceding operation, and at the same time a second pair is formed in the die.

After the terminals are sheared off, they are put into another die and the hole in each end is pierced. They are then run over a saw which cuts them exactly in half, as shown in Fig. 1. Two terminals are thus produced from each piece which is sheared off by *C*.

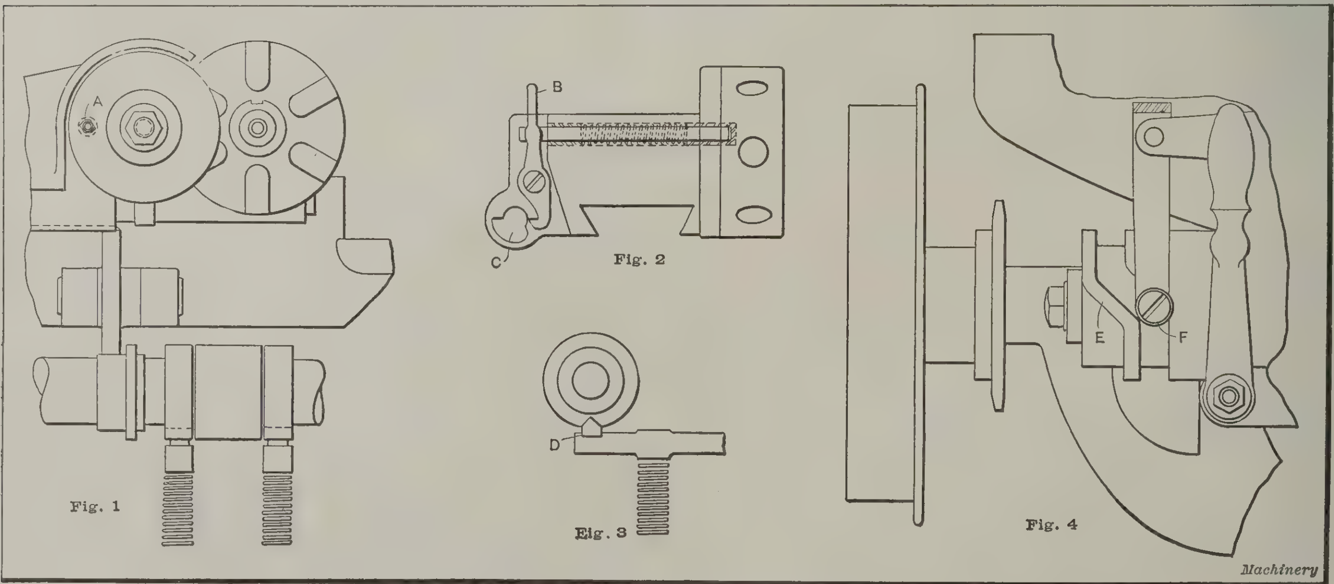
Chester, Pa. CHARLES R. ENGEL

TAKING OUT BACK-SHAFT OF A B. & S. AUTOMATIC SCREW MACHINE

In every screw machine department equipped with Brown & Sharpe automatic machines, it is necessary to take out the back-shaft of at least one or two machines a week. The back-shaft is located in the rear of the machine and carries the various operating gears and clutches, the entire machine being operated therefrom. The reason for removing the back-shaft has nothing whatever to do with the design of the machine, since it is taken out for the sole purpose of removing the gummed oil, etc. In the following, the writer will describe the only practical and correct method of removing the back-shaft, which is a very important item in the training of any screw machine operator.

If a back-shaft is taken out and replaced in such a manner that every gear does not mesh with the same teeth as it did before the shaft was removed, then the machine will be "out of time," and the entire job will have to be set up again. If all the rules stated in the following are not observed when replacing a back-shaft, the machine, although it appears to be running all right, will be running under conditions which will probably cause breakage.

Some screw machine men, when about to remove a back-shaft, mark the gears with a center-punch which is not very satisfactory after the shaft has been removed several times. Fig. 1 shows the first thing to be done when about to remove a back-shaft. The roll on the turret operating disk, the clamp nut of which is shown at *A*, should set in line with the center of the turret. The machine should be operated by hand until this effect is brought about. Fig. 2 shows a view of the turret looking from the spindle; the cam *C* should be set as shown with regard to its radial drop. This cam is used for operating lever *B*, which unlocks the turret.

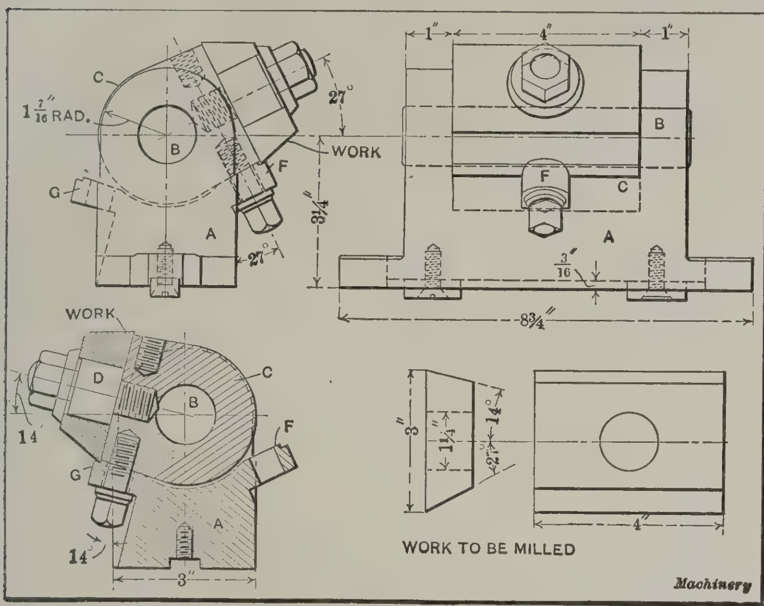


Figs. 1 to 4. Method of Taking Out the Back-shaft of a Brown & Sharpe Automatic Screw Machine

Fig. 3 shows how the clutches on the back-shaft should be set—with the notch down and engaged with the lever *D*. In Fig. 4 is shown a front view of the machine, in which the starting lever will be recognized. The cam for opening the chuck and operating the feeding of the stock is shown at *E*; *F* is the roller which rides on this cam and is shown in the position in which it should be set. When all these conditions have been observed it is safe to take out the back-shaft. NEVIN BACON

MILLING FIXTURE

The milling fixture shown in the accompanying illustration was designed for holding the cast-iron piece shown in the lower right-hand corner of the engraving. This piece has its sides milled off at different angles as indicated. The fixture consists of a base casting *A*, the flanges of which are bored out to admit shaft *B*. This shaft passes through the center casting or work-holder *C* and allows it to turn freely from stop *F* to stop *G*. In the upper left-hand corner of the engraving is shown the position of the work in the fixture when milling the 27-degree side on the work. The center block *C* is held in position while milling by a screw passed through the lug *F*. The sectional view indicates the position of the work in the fixture when milling the 14-degree side. The work itself is held to the center block *C* by a stud *D* provided with a nut and collar.



A Milling Fixture for Holding Work while milling Beveled Sides

Cincinnati, Ohio HENRY FRANZ

MEASURING SCREW MACHINE CHIPS

A common practice among screw machine workers is to measure the thickness of the chips to determine the feeds of the tools. The writer wishes to point out that this practice is misleading because of the tendency of the metal to compress in one direction and swell and stretch in the other, when separated from the bar by the cutter. In order to obtain data on the difference between the feed of the cutter and the thickness of the chips, some tests were made on a Brown & Sharpe automatic screw machine. A cam, the exact size and travel of which was known, was placed on the machine, and the machine was geared to rotate the cam at a given speed. The exact speed of the spindle was also determined, and in this way the exact feed of the cutter was known.

These tests showed that a form tool, ¼ inch wide, having a feed of 0.001 inch per revolution, cut a chip which measured 0.0025 inch when cutting brass, while a form tool ⅝ inch wide, with a feed of 0.0015 inch per revolution, cut a continuous chip 0.005 inch thick. A cut-off tool ⅛ inch wide, cutting brass and fed 0.001 inch per revolution, produced chips from 0.0015 to 0.002 inch thick. The proportions between the feed and the chip for the turret tools were slightly greater than for the cross-slide tools; that is, the chip expanded slightly more. The tests for steel indicated a smaller expansion than for brass.

Many times a cam designer is criticized by the operators for providing excessive feeds when this is not really the case, the apparent error being due to the erroneous method used by the operators in measuring the feed. The error that would result in the design of cams if the draftsman worked to data obtained by measuring the chips is, however, apparent.

NEVIN BACON

ERASING INK MARKS FROM TRACINGS

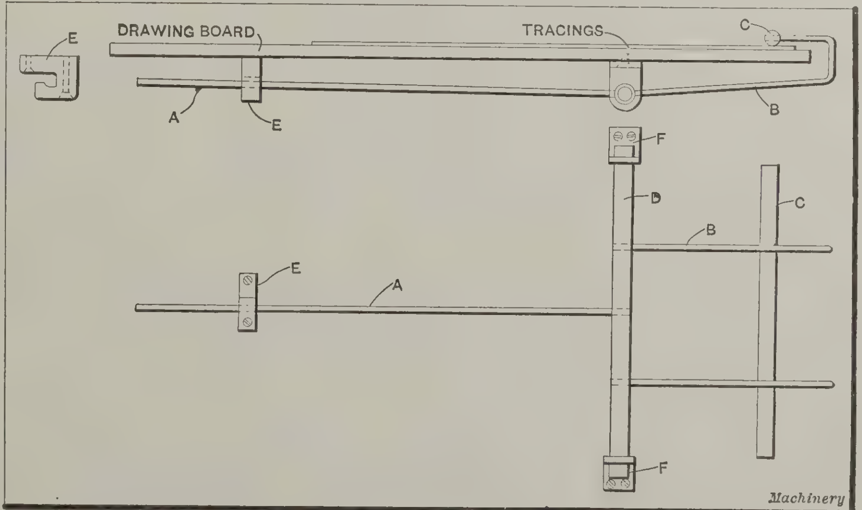
The writer wishes to add a few remarks to the discussion concerning the erasure of ink marks from tracings which appeared in the issue of MACHINERY for September. It will be found that the use of an ordinary pencil eraser on tracings will give better results than an ink eraser. The ink eraser will burn the tracing, as Mr. Allison states, if care is not taken in using it; this difficulty will not be experienced with a pencil eraser. Although a pencil eraser does not give as quick results, it will leave a much better finish on the tracing, and the use of soapstone will be unnecessary. If, however, a heavy line is to be erased, it will be found advisable to start with an ink eraser and then finish with a pencil eraser. A rather large detail can be changed on a drawing in this way, without leaving any noticeable mark. All that is required is a little patience. A. H. MYERS

York, Pa.

DRAWING-BOARD CLAMP FOR TRACINGS

When a great many tracings are used on the drawing-board at the same time, as, for example, when an assembly drawing is made, considerable trouble is experienced on account of the tracings sliding off the board. The accompanying illustration shows a special clamp made to take care of this difficulty. The tracings are placed beneath a maple stick *C*, which is located at the top of the drawing-table near the right-hand side. The clamping rod *A* is swung into the bracket *E*, and the drawings are held tightly in place. As each drawing is used it is thrown over the back of the table, the clamp still holding it in place. When a drawing is to be removed, rod *A* is taken out of the bracket, thus removing the pressure of the clamp rod which is immediately raised from the drawing-board on account of the rod *A* being the heavier part of the device. Any number of drawings can then be removed without the draftsman leaving his chair, thus saving considerable time.

Rods *A* and *B* are made of ⅜-inch cold-rolled steel and are driven into a 1-inch pipe *D*, and riveted. The maple rod *C* is 1½ inch in diameter, rods *B* being driven into it. Bracket *E* is also made of maple and is fastened to the table with two screws. Brackets *F* are made of cold-rolled steel and screwed to the board. As will be realized from the foregoing description, the whole outfit can be simply and easily made.



Arrangement for Clamping Tracings used for Reference to the Drawing Board

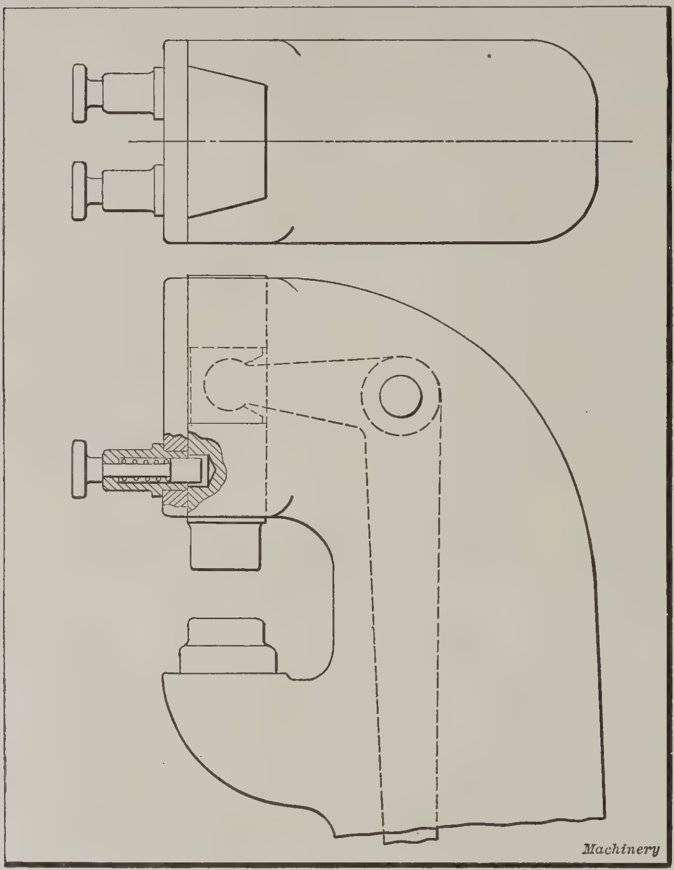
SAFETY DEVICE FOR FOOT PRESS

In a certain shop where presses were operated by foot power, the girl operators constantly got their fingers trapped between the work and the punch. Whenever this happened, if blood was drawn, about one-half of the girls were inevitably rendered useless for some time; some even fainted at the sight. Hence, it became necessary to devise a safeguard. The simple scheme shown in the illustration was adopted.



A Safety Device for a Foot Press

Two spring plungers were used which remained in the holes in the ram until they were drawn out. As both hands were required for pulling out the plungers, it was no longer possible for the girls to have their fingers in the danger zone when the ram was depressed. As presses of this type are very common in shops doing a variety of light work, the scheme described may prove of service to others.

J. Sysmore

COMBINATION FOLDING AND CURLING DIE

The accompanying illustration Fig. 3 shows a combination folding and curling die used for making the rectangular box shown in Fig. 1, which is produced from 80- to 90-pound tin.

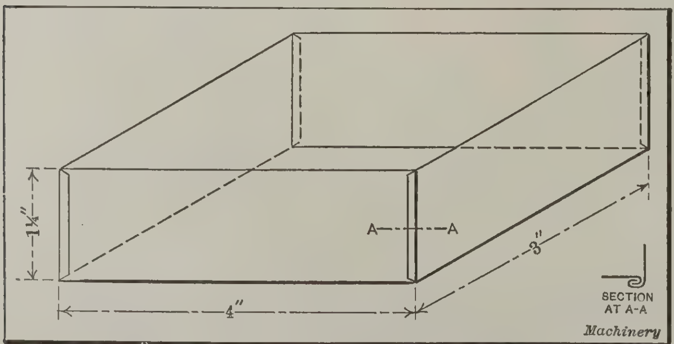


Fig. 1. The Box to be made and Section of Seam

At *A-A* is shown the section of the joint produced at the corners of the box. These corners are curled over nicely while passing through the die. The blank indicated by the lines *B* in Fig. 3 is located against the stop-pins *S* and is folded around a rectangular punch. As this punch descends the stock at the corners is slightly drawn and then follows through the narrow slit in the first section *E* of the die to the conical groove in the second section *F* where it is curled. The curled part is then flattened out in the lower section *G* of the die. The box is completed in one stroke of the die, the joints being made powder-tight. No additional trimming is required. The die can be made of machine steel with the exception of the curling blocks *D*, also shown in Fig. 2, which should be made of tool steel, hardened, and then inserted into the middle section of the die. Four curling blocks are required, two "rights" and two "lefts," of course. The blanks were cut in a previous operation, as it was more convenient than to use a large and cumbersome progressive action die.

CORRECT METHOD OF HANGING BLUEPRINTS AFTER WASHING

The writer has noticed that in most cases when blueprints have been washed, they are hung up so that they are as nearly level at the lower edge as possible. This method is not a good one, because when a print is hung so that the lower edge is practically level, the water will gravitate to this edge and hang there in globules, and the print will not be perfectly dry at this edge for hours; and in almost every case the edge is discolored.

The best way to hang blueprints for drying is to place them so that the lower edge is at an oblique angle with the horizontal; then the water will gravitate to the lowest corner. There will be no accumulation of water at other points, and the drying will be far more rapid than in the case when the sheet is hung level. This is a very small detail of drafting-room work, but it is of considerable consequence, both as regards time and the appearance of the blueprints.

St. Louis, Mo. C. H. Casebolt

* * *

A gib key should not be used to fasten a coupling on a shaft. If a key is used, it should be a headless key, or, still better, a feather.

ADVANTAGES OF N. M. T. B. A. MECHANICAL SECTION*

In order to state clearly how the National Machine Tool Builders' Association could be benefited by the formation of a mechanical section, it will be necessary to review briefly the history of the industry with relation to the forces that have been active in bringing it from obscure job shop methods, both as regards manufacturing aand selling, to the proud position of one of the largest manufacturing industries in the land. Judging from the number and character of machine tools of foreign make purchased prior to 1875, and still in use in some railway division shops, the machine tool industry of those days must certainly have been in its infancy. There are men still active or recently passed away who have been in touch with the industry during all the years since then, and who are responsible for the marvelous changes that have taken place. The story of their lives is the story of the development of the industry. Few of these men were distinguished as salesmen. Financiering and accounting in the modern sense were unknown to them, but they were able mechanics—master workmen of their day, possessed of almost egotistical pride in personal accomplishments in their line. Guarding jealously the product of their own brain, they for the most part respected the rights of competitors, whether registered in the patent office or not.

These men had their faults, it is true, growing out of conditions then existing. They traveled little, they never met their competitors face to face, and knew nothing of them except through their dealer, who visited the shops occasionally to place stock orders for the requirements of the next six months or year. It is, therefore, little wonder that a competitor was regarded as an enemy, incompetent and unscrupulous. These were the golden days for the dealer. Factory sales organizations were unknown, and selling costs were at a minimum. The manufacturer knew nothing of shop costs, and sale prices were made to harmonize with the sale prices of competitors, with the result that profits to those engaged in the industry were small in almost any line requiring high-grade effort.

Out of these conditions, bad as they were with relation to the commercial end of the business, came a mighty strength, for as early as 1893 all the nations of Europe had discovered that this country was producing metal working machinery superior to that which could be found elsewhere. Was it superior sales organizations that gave us almost exclusive control of this great market for the next ten years and established a reputation for American tools that still lingers in spite of later developments abroad?

As proof of this statement, it may be well to cite an incident touching this point. The author was present at an interview in the factory office between one of these peerless pioneer mechanics and a European purchasing agent, who was regarded as a joke, and whose proposal to sell quantities of the manufacturer's product abroad was almost turned down. This mechanical man simply could not understand why any one would wish to come all the way from Europe to purchase the product of his little shop. He was inclined to regard his visitor with suspicion.

Since that day the tremendous increase in the demand for metal working machinery both at home and abroad has been working a transformation in the management and ownership of the business. That this transformation is natural, logical, and inevitable, the author shall not attempt to dispute; but it carries with it dangers that must be guarded against. We must occasionally get back to first principles and not lose sight of the reason why Europeans first came to extensively purchase the product of our shops, with practically no solicitation. The familiar title, the old man or the boss, the master workman of yore, who worked at the drawing-board, bench, or desk, is now transformed to the title of "president" or "general manager", and his knowledge of shop conditions is gathered from a condensed record of costs prepared by an expert in his line, all of which is well and necessary, but which marks a distinct change in the relative importance of the commercial and mechanical departments.

Since the organization of the Machine Tool Builders' Association there has been a noticeable improvement in many directions, and all honor to those leaders who have been its promoters and ardent supporters. Competitors now meet on a basis of real friendship; but something has been lost in the passing of the old professional spirit and pride with reference to mechanical things that will ultimately work great injury. This mechanical spirit that once dominated all, is now dominated by the commercial end. And while the author does not expect that the mechanical end can ever be reinstated in its old position of supreme importance, when coping with a sales organization that reaches around the world, we must not lose sight of the fact that in order to be successful in the markets of the world we must be able to offer at all times the best and the most advanced design to be found anywhere. If this can, in a measure, be brought about, great benefit may come to the Machine Tool Builders' Association by the formation of a mechanical section.

It is more difficult in these days when all-around skilled help is at a premium, for the superintendent and foreman to get away from their work, than for any other set of men connected with the plant. However, this does not apply with the same force to men connected with the designing end of the business. Our trade papers are alert to secure and publish anything of general interest to shop men and designers, and nearly all connected with the industry depend largely on these papers for their information, but, of course, there are lacking the benefits that would come from the personal touch.

It would seem that the annual convention could be extended over five or six days, with the last two or three days given up entirely to subjects that would be of general interest and benefit to the builders and designers of machine tools; or in place of the longer session, a three days' session with meetings held by the different departments in separate rooms, would, perhaps, be preferable.

Another subject for discussion is the advisability of holding in New York, by the National Machine Tool Builders' Association, at stated intervals of five or more years, an exhibition of metal working machinery, restricting each exhibitor to one machine of a type, and permitting no machine to be exhibited that did not show noteworthy improvement over the machine shown by the same exhibitor at the previous exhibition. While this thing may not be practical, the author is convinced that if it could be worked successfully, it would not only be a stimulus in the design of new machines, but would be of great value to the sales end of the business, as it would be sure to be attended by buyers of machinery from all parts of the world.

The whole thought is this: We must first have machines, and then salesmen to introduce them, if we are to maintain ourselves in the foreign markets, as well as in the home markets, for our experience during the past year shows clearly whither we are tending as regards protection. Let us develop the highest grade of commercial spirit, and use if possible this same instrumentality to better our product, to the end that in a measure the professional mechanical spirit of yore be re-established, so that our foreign competitor, should he ever find his passage through the customs house unobstructed, will be greeted everywhere with the sign of the uplifted hand.

* Abstract of paper by E. J. Kearney, of the Kearney & Trecker Co., Milwaukee, Wis., read before the convention of the National Machine Tool Builders' Association, in New York City, October 17, 1912.

* * *

In a paper read before the Iron and Steel Institute, Great Britain, Mr. C. Chappell gave some interesting information relating to the influence of carbon on the corrodibility of iron. He stated that in rolled and annealed steels the corrodibility rises with the carbon content to a maximum at the saturation point (0.89 per cent carbon), and falls with a further increase of carbon. In hardened and tempered steel a continuous rise in corrodibility takes place with an increase of carbon up to a carbon content of 0.96 per cent. Quenching increases the corrodibility to a maximum, while annealing tends to reduce it to a minimum.

NEW MACHINERY AND TOOLS

THE COMPLETE MONTHLY RECORD OF NEW DESIGNS AND IMPROVEMENTS IN AMERICAN METAL-WORKING MACHINERY AND TOOLS

THE MUELLER 18-INCH HEAVY-DUTY ENGINE LATHE

The Mueller Machine Tool Co., Cincinnati, O., has recently added to its line the 18-inch heavy-duty engine lathe illustrated in Fig. 1. This machine swings 18½ inches over the ways, 13¼ inches over the carriage, and takes work up to 2 feet 4½ inches between the centers.

The headstock is of massive construction and is ribbed and cross-ribbed to secure the maximum rigidity. The cone pulley has three steps of 9 1/4 inches, 11 3/16 inches and 13 5/32 inches diameter, and double belting 3 1/2 inches wide is used for driving, thus providing an abundance of power for the heaviest classes of service. The cone pulley is locked to or released from the face gear by a spring pull-pin.

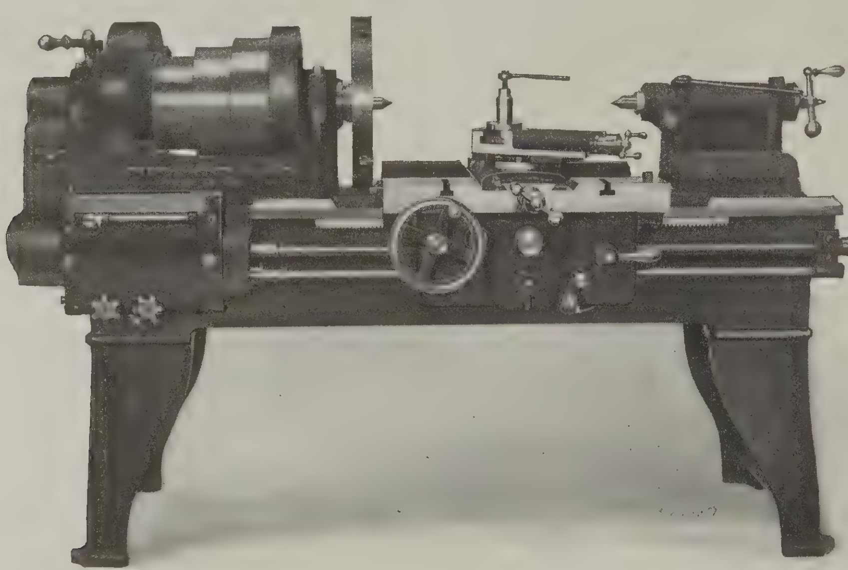

Fig. 1. The Mueller 18-inch Heavy-duty Engine Lathe

The tailstock is arranged with two plug clamps for locking the tailstock spindle without throwing it out of line. Both the headstock and tailstock are set off center, so that large diameters can be turned without having the bottom slide on the carriage overhang its bearings. The tailstock is clamped to the bed by means of two ¾-inch bolts; the tail spindle has a movement of 8¼ inches, and a bearing 2½ inches in diameter.

The work spindle is made of high-carbon crucible steel; it has a 1 9/16-inch hole through its entire length, and is fitted for a No. 4 Morse taper. The spindle boxes are of phosphor-bronze, bored and hand scraped to an accurate fit. The bearings are oiled through sight-feed oilers and felt pads which dip into a reservoir. The oil supplied to the bearings by this method is freed from all foreign matter, thus insuring perfect lubrication. The thrust collar is of hardened steel and the end motion is taken up by a nut at the end of the spindle. Nine spindle speeds are provided, ranging in geometrical progression from 13 to 300. The double back-gears on this machine are of the slip-gear type. A lever which is conveniently located at the front of the machine provides means for changing from low to high speed or *vice versa.* The back-gear ratios are 3½ to 1, and 10½ to 1.

This lathe will cut 45 thread pitches ranging from 2 to 60 per inch, including 11½ inch pipe thread. All changes are obtained within the quick change gear box. The ends of the shafts of the gear box and the reversing gears on the head are arranged to receive change-gears for special and metric thread cutting. All threads can be cut without the removal of a gear, and there is a chasing dial on the carriage for "catching" the threads. The turning feeds are positively geared, and are four times the thread feeds. They can be started, stopped or reversed in the apron or head, for either a cross or lateral feed motion, but only when the lead-screw nut is disengaged.

The carriage has exceptionally long bearings on the V's for its entire length. It has an adjustable taper gib the full length of its bearing against the rear side of the bed, thus eliminating the possibility of any twisting of the carriage while extra heavy cuts are being taken. A long shear wiper and oiler is fastened to each end of the carriage bearing on the shear; this arrangement automatically wipes the shear free from all dirt and chips, and oils it as the carriage moves along. The upper slide of the compound rest is bolted to the swivel base with four screws, which insures absolute rigidity.

The apron is of the rectangular box type, in which all the bearings for the gears and screws are cast integral with the apron itself. All gears are provided with bearings on both sides and the studs are of hardened and ground steel. The feeds are so arranged that only one feed can be in operation at a time. The lead-screw is 1 9/16 inch in diameter, and has a four pitch thread; it is only rotated when the lathe is engaged in screw cutting. The lead- and feed-screws for this lathe are cut from a master screw, thus insuring the greatest possible accuracy.

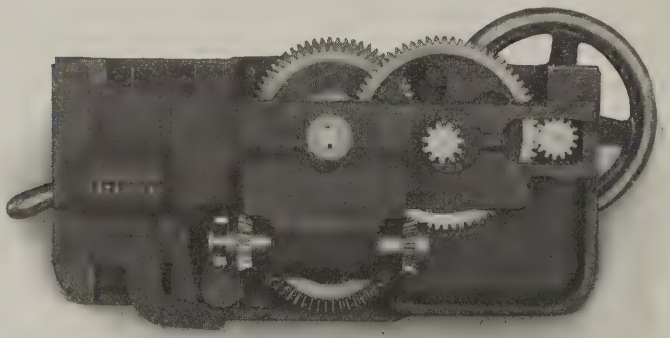

Fig. 2. Rear View of the Lathe Apron

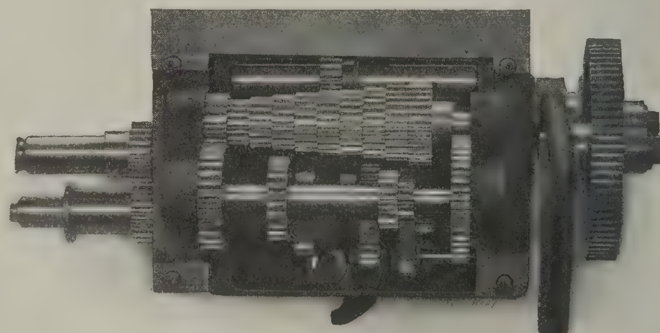

Fig. 3. Gear-box of the Mueller Lathe

The bed is designed with an unusual vertical depth and is firmly braced through its entire length with heavy cross girths, capable of absorbing the vibration of the heaviest cut. The rear bearing is flat. The countershaft has double friction pulleys, 14 inches in diameter. It is fitted with heavy bearings and hangers which insure rigidity and long life.

All gears in the quick change gear box are of steel and have chamfered teeth. Steel gears are also liberally distributed throughout the machine in all places where severe strains are encountered. The greatest care is taken in cutting all of

these gears in order to secure the maximum accuracy in the teeth and consequently smooth and noiseless operation. All gearing on the lathe is completely enclosed. The regular equipment consists of two faceplates for large and small stock, steady-rest, follow-rest, countershaft, and the necessary wrenches. The lathe can also be equipped with direct-connected motor drive and with a longer bed, when so required.

MILWAUKEE UPRIGHT DRILLING MACHINES

Two upright drilling machines built by the Richards Machine Co., 1129 Davis St., Milwaukee, Wis., are illustrated in Figs. 1 and 2. Fig. 1 shows the 20-inch machine equipped with back-gears, power feed and a combined wheel-and-lever feed. This machine can also be obtained without the back-gears and power feed, and with either a combined wheel-and-lever feed or a plain lever feed, as desired.

The chief feature of this machine is the method used in disengaging the power feed, when it is desired to use the wheel or lever feed. This device consists of an arm carrying the bevel gear, worm and worm shaft, which is operated by an eccentric for disengaging the bevel driving gears. In the illustration the lever for operating this eccentric is shown in the position it occupies when the power feed is being used. To disengage the power feed, this small lever is simply pulled towards the front of the machine.

There are eight changes of spindle speed and twenty-four changes of feed. The back-gears for the slow speed of the spindle are enclosed in the upper cone pulleys. Power for the automatic feed is obtained from the upper cone spindle, and

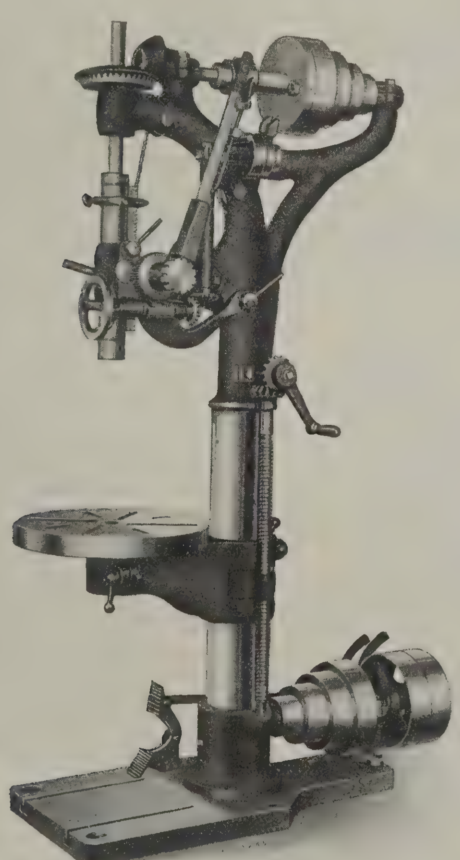

Fig. 1. Upright Drilling Machine built by Richards Machine Co.

is transmitted to the drill spindle by belt and the worm and bevel gearing shown.

The principal dimensions are as follows: Movement of drill spindle, 9 inches; greatest distance from end of spindle to base, 41 inches; greatest distance from end of spindle to table, 25 inches; height over-all, 69 inches; diameter of table, 17 inches; hole in spindle, No. 3 Morse taper. The machine will drill to the center of a 20-inch circle.

The upright drilling machine shown in Fig. 2 is provided with a sliding head, is back-geared, has positive feed and a number of interesting features not found in the other machine. Among these might be mentioned the gear-box for giving a positive feed to the spindle, and the device for effecting the feed changes. This device consists of two levers located directly below the gear-box, which operate a sliding gear for changing the rate of feed. These levers are properly located by a notched plate which they engage. By moving the lower lever up or down, three changes of feed are obtained, and by

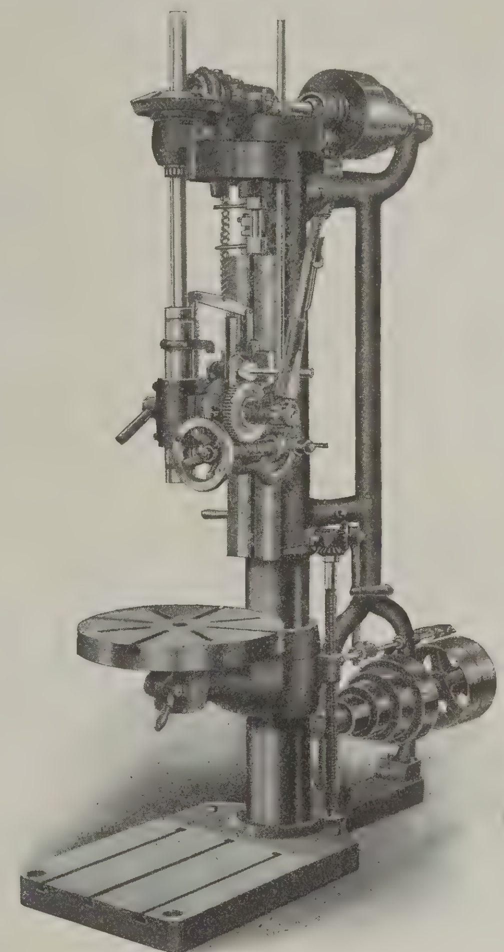

Fig. 2. Upright Drilling Machine of Sliding-head Type

shifting the upper lever into the "slow" or "fast" notch, six changes of feed are secured. With the top lever in the "slow" notch and the lower lever placed successively in the three notches, the feeds are: 0.003, 0.007 and 0.011 inch per revolution of the spindle. With the upper lever in the "fast" notch and the lower lever shifted to the three positions, the feeds are: 0.023, 0.060 and 0.095 inch per revolution of the spindle.

The back-gears are enclosed in the upper cone pulleys and are thus protected from dust and dirt. The principal dimensions of the machine shown in Fig. 2 are as follows: Movement of drill spindle, 10⅜ inches; movement of sliding head, 20 inches; greatest distance from spindle to base, 50 inches; least distance from spindle to base, 19 inches; greatest distance from table to spindle, 37 inches; diameter of table, 20 inches; height over-all, 84 inches; hole in spindle, No. 4 Morse taper; drilling capacity, to the center of a 24¾-inch circle. The weights of the machines shown in Figs. 1 and 2 are 600 and 1500 pounds, respectively.

CINCINNATI PRECISION LATHE WITH SCREW-CUTTING ATTACHMENT

The latest design of friction-driven bench lathe built by the Cincinnati Precision Lathe Co., Cincinnati, Ohio, is shown by the front and rear views, Figs. 1 and 2. This lathe has an improved friction drive and a slide-rest screw-cutting attachment. The difference between the friction-driving mechanism of this lathe and those formerly built is in the control and the construction of the driven disk. The latter,

instead of being a solid piece, is formed of two members which are separated by a series of coiled springs, thus forming a spring tension or "cushion" disk. These two parts are shown in detail in Fig. 3. In addition to springs, there are a number of steel guiding studs near the circumference of the disk and a large projecting hub in the center, all of which engage holes in the upper member. The guiding studs and hub are accurately fitted and there is also a bearing fit between the flange on the lower disk and the periphery of the upper disk, which insures a uniform tension at all points on the horizontal friction surface.

A further advantage claimed for this disk is that there is a very slight tendency of the horizontal friction plate to incline with relation to the driving shaft when the friction driving wheel is located outside of the center. This movement, while very slight, is just sufficient to release that part of the friction filler material which would otherwise bear against the outer and more rapidly moving surfaces on the driven disk. In this way the sliding action between the two surfaces, which is common to a rigid-disk friction drive, is obviated and the loss of friction material reduced. As the driving disk is applied on both sides of the driven disk center for obtaining forward and reverse speeds, the face or periphery of the driving disk wears uniformly or parallel to the friction driving shaft. As the driving disk approaches the center of the driven member, the spring tension increases slightly because the wheel comes directly under an increasing number of springs as it approaches the central and higher speed positions. In case a heavier spring tension is desired, the lower driving shaft can be raised by means of eccentric bushings provided.

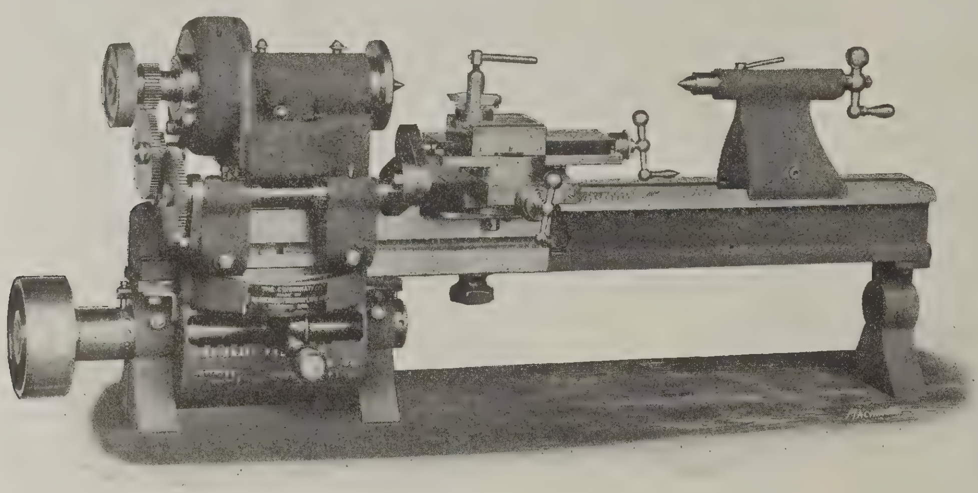

Fig. 1. Cincinnati Friction-driven Precision Lathe with Slide-rest Screw-cutting Attachment

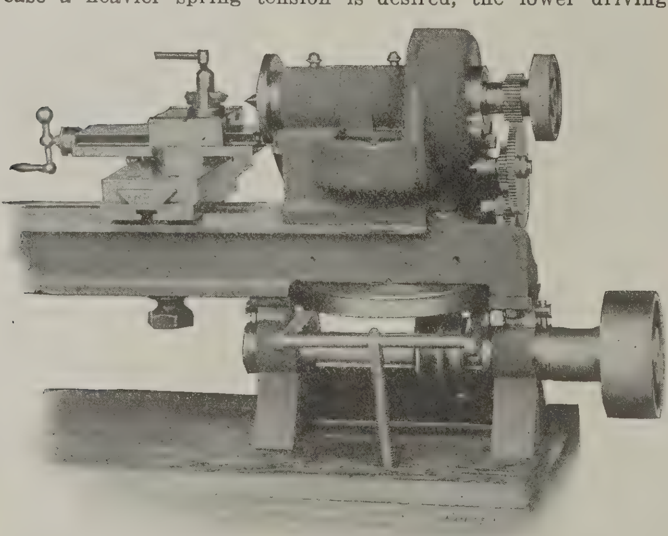

Fig. 2. Rear View of Headstock and Friction Drive, showing Foot-pedal Release

With the horizontal friction disk as the driven member, if the lathe should be overloaded and the frictions caused to slip, the driving disk would continue to revolve and the wear would be uniform instead of forming flat spots. It is claimed that the location of the driving pulley at the base and the use of the cushioned disk reduces vibration to a minimum. The friction hand-control lever for varying the speeds has a circular inner end which engages a recess or slot in the hub of the driving disk. The latter slides easily on the friction driving shaft and a longitudinal key inserted in the shaft, when the friction members are disengaged. The lower side of the control hand lever is so shaped as to readily drop into notches in the front gear cover, for retaining the friction driving wheel in any desired speed location on the driven disk.

Fig. 3. The Two Parts of the Spring-tension or Cushion Friction Disk

The rear view of the lathe head and friction drive shown in Fig. 2 illustrates the foot pedal release that is applied to this lathe. This releasing mechanism consists of two arms or levers, on the ends of which are bushed fiber rollers so arranged that when pressure is applied to the foot pedal the friction disk surface is raised, thereby disengaging the friction driving member. At the same time, the rollers act as a brake and stop the machine almost instantly. The forward or reverse speed changes can be quickly made, and, as the spindle can be stopped and started very quickly, threads can be cut close to a shoulder with safety. The spring seen between the bench and lever cross-arm is for holding the lifting levers away from the disk when the lathe is in motion. The foot pedal is pushed under a retaining step on the floor when the lathe is to remain stationary.

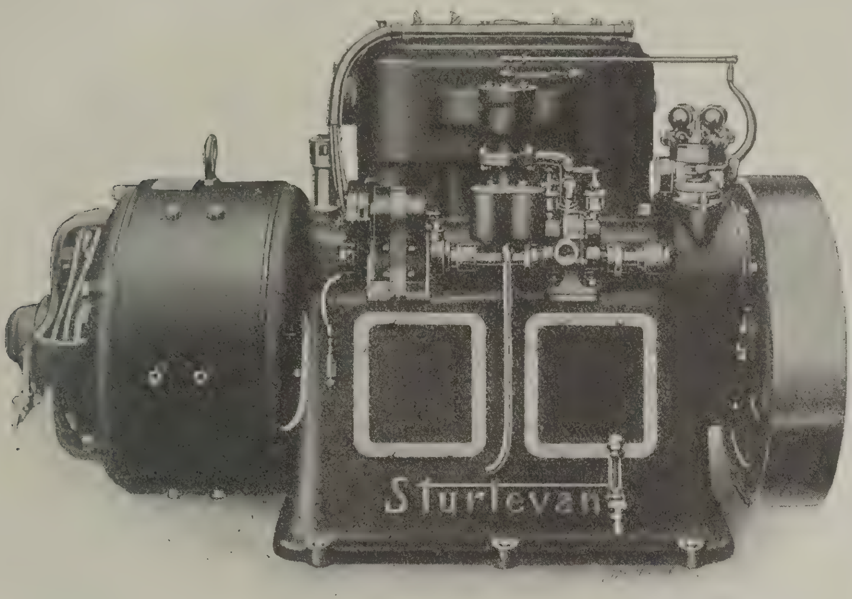
STURTEVANT GASOLINE-ELECTRIC GENERATING SETS

The B. F. Sturtevant Co., Hyde Park, Mass., is now building gasoline-electric generating sets designed to supply the demand for units that will be easy and inexpensive to operate, in places where electric power is not available. These sets are intended to be used in direct connection with lighting and power circuits and not through a storage battery, although they can be so arranged if desired. The design, workmanship and efficient governor control are said to insure constant voltage through wide variations of load, so that the use of a storage battery to equalize fluctuations of voltage is not necessary.

These generating sets are built in three sizes of five, ten and fifteen kilowatts capacity, capable of lighting 200, 400 or 600 twenty-candlepower tungsten lamps, respectively. The five-kilowatt size is illustrated herewith. These sets consist of a Sturtevant gasoline engine directly connected to a Sturtevant direct-current electric generator. The engine is of the four-cycle, water-cooled, vertical type, having either four or six cylinders, according to the size of the unit. The bore of the cylinders used in the ten and fifteen kilowatt sizes is 4 inches, and the stroke 6 inches, whereas the five-kilowatt engine has a 3¼-inch bore and a 5-inch stroke. The cylinders

of the two larger sizes are cast in pairs and have T-shaped heads with inlet valves on one side and exhaust valves on the other. The cylinders of the five-kilowatt engine are cast *en bloc* with inlet and exhaust valves on the same side. In both cases the water jackets are integral.

The cylinders are accurately bored and ground to size, and provision is made for the easy removal of the valves for inspection or regrinding. The pistons have four rings and the piston pins are of large diameter and are made of hardened steel. Both the piston and pin are accurately ground and finished. The connecting-rods are exceptionally long, of I-section and are drop-forged from high-grade steel. The inlet and exhaust valves are of nickel steel. The valves for the ten and fifteen kilowatt units are operated by two camshafts, whereas one camshaft is used on the five-kilowatt size. The cams are integral with their shafts and are hardened and ground to the proper shape. The engine bases of the ten and fifteen kilowatt sets are made of two castings, split horizontally on the center line with the crankshaft bearings. A single casting is used for the base of the five-kilowatt unit and the generator is attached directly to the engine base, as the illustration shows. A separate sub-base for the engine and generator is provided on the larger sizes.



Sturtevant Five-kilowatt Gasoline-electric Generating Set

The crankshaft is made of 3½ per cent nickel steel which is of exceptionally high tensile strength and has undergone careful heat-treatment. All pins and journals are accurately ground. The most improved system of forced lubrication is used, the oil being furnished to all bearings under a pressure of 20 pounds, by means of a gear pump located in the engine base. The oil enters the main bearings and flows through the crankshaft (which is drilled for that purpose) to the crankpins, whence it passes up the connecting-rods to the piston pins. The oil spray thrown off by the centrifugal action of the crankshaft covers the piston and cylinder walls. When the oil falls back into the base it passes through a filter before being used again.

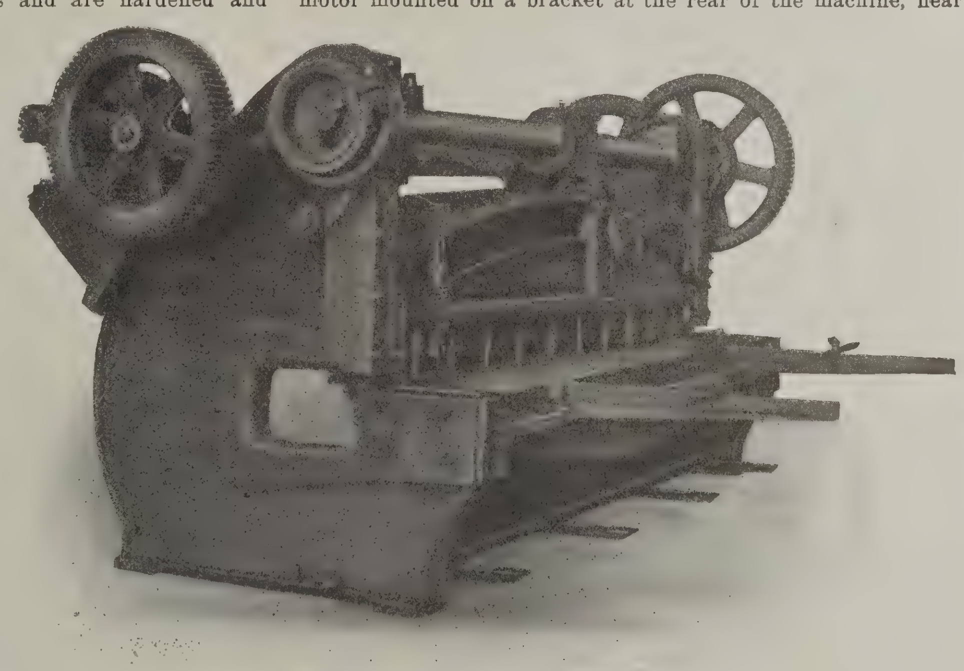
The engine is controlled by a throttling governor of the centrifugal type, operated through bevel gears from the end of the crankshaft. The motion of the governor is transmitted to a throttle valve placed in the inlet manifold. This governor is said to regulate the speed of the engine so accurately between no load and full load, that the voltage variations due to sudden changes in the load are imperceptible and no storage battery is necessary to maintain a constant voltage. The engine is equipped with a high-tension Bosch magneto, which is mounted on the base and is operated from the camshaft. The same type of generator that has been used in connection with Sturtevant steam engines of the U. S. Navy and merchant marine, is used for these gasoline power units. The generator is designed to require a minimum amount of attention. Both the engine and generator are capable of operating under an overload of 25 per cent for two hours.

NIAGARA MOTOR-DRIVEN PLATE SHEAR

A plate gap-shear recently designed and built by the Niagara Machine & Tool Works, Buffalo, N. Y., is shown herewith. This machine has the convenient means for adjusting the bed, crosshead and gibs, common to all large shears built by this company. The motion is controlled by a positive clutch which can be operated by a foot treadle, and the machine stops automatically when the crosshead reaches the highest position. The "hold-down" is raised and lowered by two cams, keyed to opposite ends of the crankshaft. The latter is forged from high-carbon steel.

The arrangement for adjusting the back gage attached to the cutter-bar is a new feature. This gage can be quickly adjusted by the operator, when he stands in front of the machine, by means of the handwheel seen in the center of the shear. The motion is transmitted to the gage by shafting, bevel gears and feed-screws at the rear. The gage always remains in a position parallel to the knives.

This shear is driven by a direct-connected, 15-horsepower motor mounted on a bracket at the rear of the machine, near the gearing seen to the extreme left in the illustration. It has a cutting length of 126 inches and will cut soft steel up to ¼ inch thick. The weight of the shear is about 22,000 pounds.



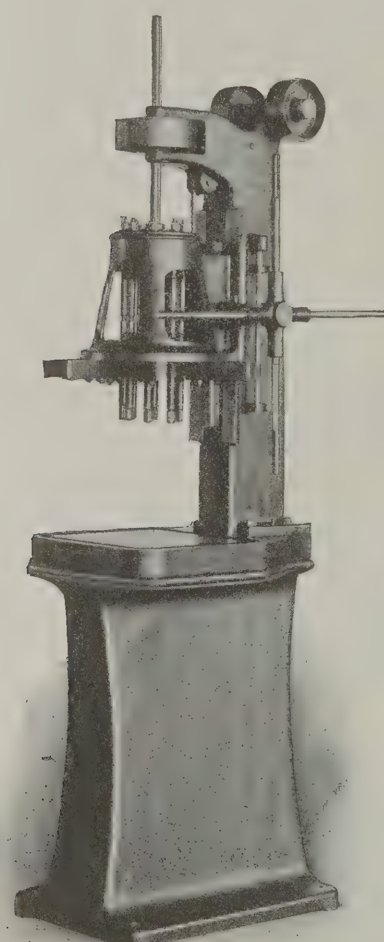
Niagara Motor-driven Plate Shear

THE NATCO NO. 9 MULTIPLE DRILLER

The National Automatic Tool Co., Richmond, Ind., has added to its line of multiple drillers, a smaller machine which in-

cludes a number of new features in its design. This machine is known as the Natco No. 9, Type D, and has been designed with a view of replacing multiple spindle drill fixtures which are not only entirely special, but which require a large drilling machine to drive them. This machine can be arranged for either bench or floor use, as it is made with a separate base upon which the machine is mounted for service as a floor drill. The illustration shows the machine set up in this manner, while for use on a bench, it would, of course, be taken from the base.

The method of indépendently changing the spindle speeds in use on the other multiple drillers made by this company is not used on the present machine, as the maximum size of drills for which it is intended is ¼ inch. The head feeds down to the work by means of a capstan operating a rack and pinion; the head has a bearing 11½ inches in width and a maximum travel of 12 inches. It is counterbalanced by means of a chain and weight, and is provided with adjustable stops for drilling holes to a specified depth. Adjustable gibs provide means to take up any wear that may develop, and the machine has a maximum capacity for a circle 8⅜ inches in diameter.



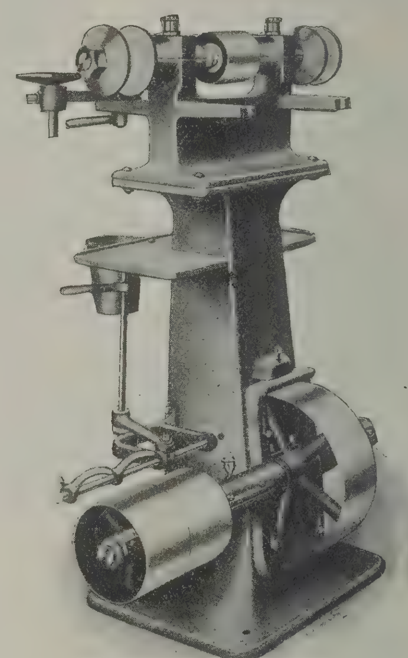
The National Automatic Tool Co.'s No. 9 Multiple Drilling Machine

The same rail and joint construction is used on this machine as on the larger sizes of multiple drillers built by this company. The rails are made of steel and have a bearing of 4 inches for the spindle. They are provided with ball thrust bearings, means of adjusting for wear and ample oiling facilities. Two sizes of rails are used which are known as the No. 1 and No. 2 size. The largest drill for the No. 1 size is 3/16 inch, with minimum centers 21/32 inch; for the No. 2 rail, the largest drill used is 1/4 inch, with minimum centers 25/32. If closer centers are desired, special rails can be furnished. The rails are easily changed from one layout to another. The base has a working surface 14½ inches square, and the surface over the oil groove is 17¼ by 18¼ inches. The maximum distance from the end of the spindle to the base is 15 inches, and the minimum distance 3 inches.

This machine can also be equipped with cluster boxes in which all of the spindles are permanently located. With a cluster box equipment, it is possible to drill a larger number of holes than with the rails, the number depending upon the material to be drilled and the size of the holes. The use of these cluster boxes saves the time occupied in changing rails from one layout to another and any number of cluster boxes can be used on a given machine, as all boxes are made interchangeable. The advantages of the cluster boxes for strictly interchangeable manufacturing are apparent. The illustration shows the machine equipped for belt drive, but individual motor drive can be furnished if so desired.

ST. LOUIS GRINDER

The grinder shown in the illustration is an improved design now being built by the St. Louis Machine Tool Co., 1209 Gratiot St., St. Louis, Mo. The countershaft of this grinder is carried by a frame that is attached to the column by accurately milled square gibs. With this construction, the countershaft is kept in accurate alignment and the tension of the belt can easily be varied by simply raising or lowering the frame, a suitable adjusting screw being provided for that purpose. By driving the spindle from below, the wheels run smoothly, as the pull of the belt is downward against the rigid body of the machine.

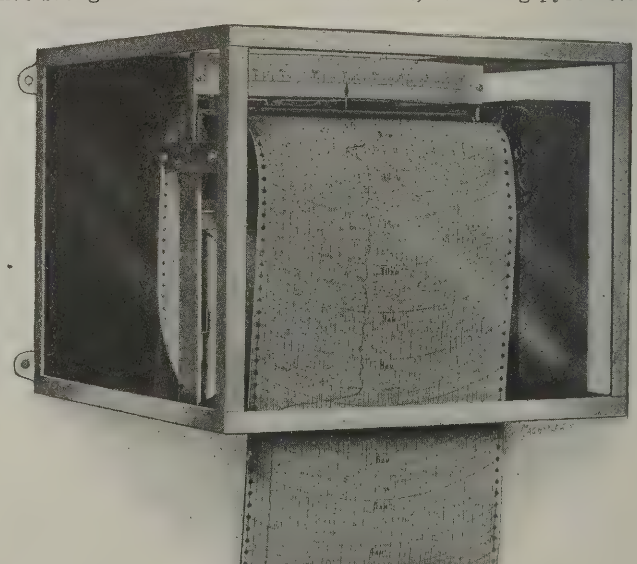


Rear View of St Louis Grinder showing Method of Attaching Countershaft

The spindle of this grinder is made of 0.40 per cent carbon steel. The boxes are dust-proof and the rests are of an improved design requiring a shorter bracket than the straight type. As the illustration shows, the machine is also equipped with back-rests for attaching wheel guaras or fixtures. The wheel guard is a simple and effective design consisting of a steel channel rolled to a segment of a circle and reinforced by a heavy cast-iron bracket riveted to the inside flange. This bracket is attached to the back-rest by a bolt which slides in the slot, thus allowing the guard to be adjusted backward as the wheel wears. The lips of the guard can be kept close to the wheel where they are not in the operator's way. These grinders are made in six sizes.

CONTINUOUS-CHART RECORDING PYROMETER

The Brown Instrument Co., of Philadelphia, Pa., and its associate company, the Keystone Electrical Instrument Co., have brought out a new continuous-chart, recording pyrometer.



Continuous-chart Recording Instrument for Indicating Temperatures, Volts, Amperes, etc.

This instrument is designed more particularly for use as a pyrometer, but can also be employed for indicating volts, amperes, revolutions per minute, mechanical operations, etc.,

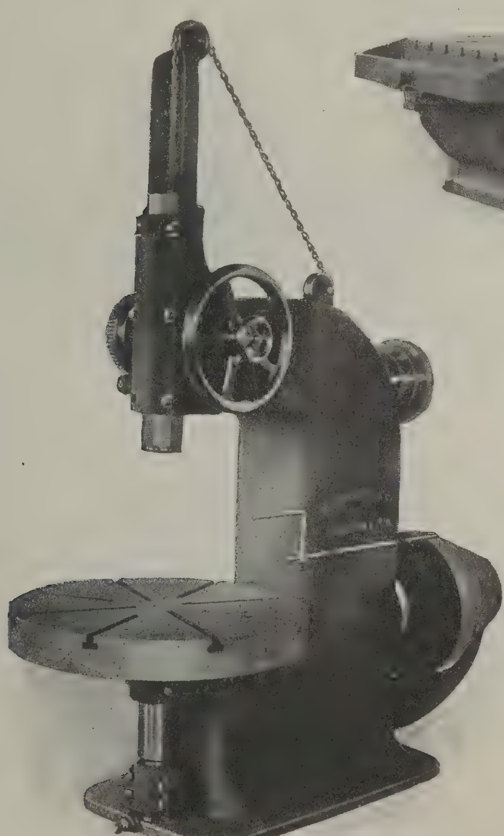
where a small current of electricity is required to operate a recording instrument.

The construction of this instrument is simple, and the works are enclosed in a plate-glass case. It is of the frictionless type, the pen forming a line by making single dots of ink on the paper at short intervals of ten seconds or a minute, as desired. These dots practically form a continuous line. The instrument carries a roll of recording paper which will last six months. This paper travels a little over an inch an hour, so that it is not necessary to change the charts daily and a continuous record can be secured.

BICKFORD VERTICAL CHUCKING MACHINE

The vertical chucking machine shown in the accompanying engraving has been designed to supply the demand for a low-priced tool for boring car wheels, gears, pulleys, and similar work. The tool-slide of this machine is octagonal in shape and is counterbalanced. The spindle feed is operated through a large friction worm-gear on the left side of the head, which runs in oil. This worm-gear is driven through a geared feed-shaft connecting with the main driving shaft by the four-step feed cones seen at the rear, which gives four changes of feed. A large handwheel is provided for hand adjustment and a quick-return movement, and the friction feed is engaged by means of a small handwheel in the center of the large wheel.

The table is driven through heavy bevel gears and it has a large spindle fitted with adjustable boxes. The weight of the table and work is taken by a hardened and ground steel step which is submerged in oil and is adjustable. The frame of the machine is very rigid. The driving shaft is mounted in three long bearings and the outer end is supported by a heavy arm attached to the frame. This machine can be equipped with detachable chuck jaws or a special chuck table. The swing is 37 inches, and the total movement of the spindle, 29⅛ inches. It is built by H. Bickford & Co., Lakeport, N. H.



Bickford Vertical Chucking Machine

INGERSOLL MILLING MACHINE

The Ingersoll Milling Machine Co., Rockford, Ill., recently installed the large five-head, six-spindle horizontal milling machine shown in Fig. 1, in one of the largest tractor plants in this country. This machine is used for milling forty and sixty horsepower tractor engine frames, as indicated in Fig. 2. These frames are finished complete on this machine and five cutters operate simultaneously. The largest of these cutters has a diameter of 36 inches.

The bed and table of the machine are of the conventional planer-type construction, and the wings upon which the housings are mounted are cast integral with the bed. The housings and cross-rail are also made in one piece, and because of this feature, the machine is known as the "fixed rail" type. The casting forming the housings and cross-rail, is very large and heavy, as the illustration indicates. The face or bearing for the saddles is 21 inches wide and the housings are 36 inches deep. The distance from the top of the table to the under side of the rail is 42 inches.

As previously mentioned, the machine has five heads, three of which are horizontal and two vertical. One of the horizontal heads is mounted on the left-hand housing, and on the right-hand side there is a main head carrying an auxiliary head and also an extra spindle which passes through the main spindle. The horizontal heads on both sides are counterbalanced and can be moved simultaneously or independently.

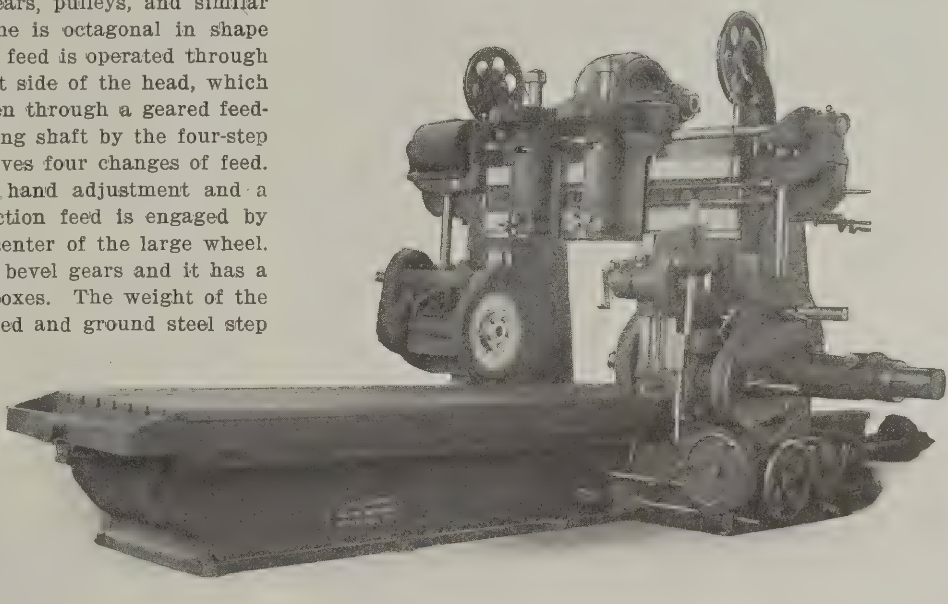


Fig. 1. Ingersoll Five-head, Six-spindle Milling Machine

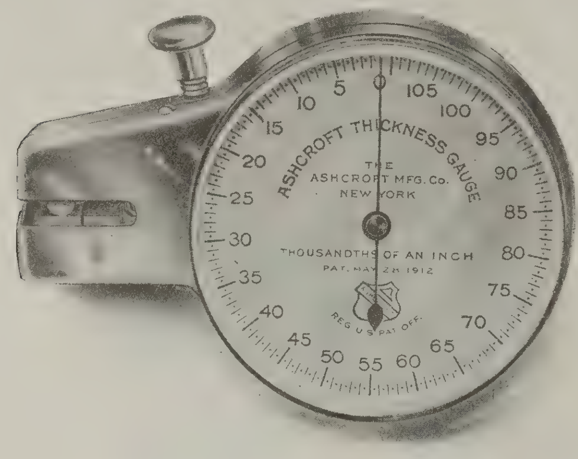
The right-hand horizontal head is the most massive, as the illustration shows. Its main spindle is of the faceplate-drive type and is arranged to carry cutters varying from 24 to 36 inches in diameter. The spindle which passes through this main spindle, is used for driving small cutters. It is 4½ inches in diameter and has an in-and-out adjustment of 18 inches. The auxiliary head or saddle is in front of the main spindle and also has a 4½-inch spindle which runs in a sleeve or quill 6⅛ inches in diameter. The spindle has an in-and-out hand adjustment of 6 inches, and the saddle itself has a vertical adjustment of 18 inches on the main saddle.

Fig. 2. Ingersoll Machine Milling Tractor Engine Frames

The left-hand horizontal head is also of the faceplate-drive type, cutters of large diameter being bolted directly to the spindle driving gear. The vertical spindles are 4½ inches in diameter. The drive is a 40 H. P. direct-connected motor.

ASHCROFT THICKNESS GAGE FOR SHEET MATERIALS

The Ashcroft thickness gage shown in the illustration is a convenient and accurate instrument for quickly measuring the thickness of sheet metal, sheet rubber, leather, paper, boxboard or any sheet material not exceeding 0.110 inch in thickness. It is of a convenient size to be held in the hands, and the material to be measured is inserted between the jaws which are opened by pressing a push-button with the finger.



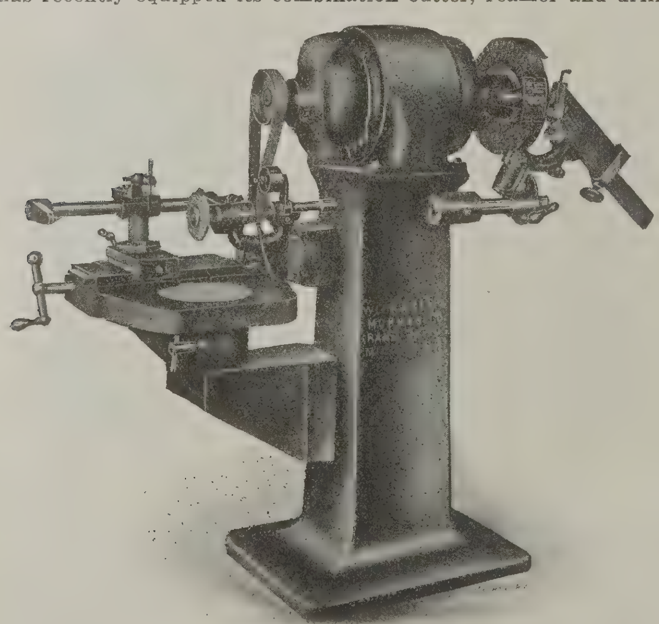
Ashcroft Thickness Gage for Sheet Materials

When pressure on the push-button is released, the jaws automatically close and the thickness of the material is indicated on the dial.

The white enamelled dial is easy to read, as the graduations stand out distinctly. The dashes represent thousandths, the dots one-half thousandths, and the points equidistant between the dots and dashes, one-quarter thousandths of an inch. The gage has no sliding parts, the movement being mounted on steel pivots. Friction and wear are thus reduced to a minimum. This gage can be carried in the vest pocket, if desired, and, with proper care, will last for years. It has been placed on the market by the Ashcroft Mfg. Co., 85 Liberty St., New York. The price of the instrument is $10.

WILMARTH & MORMAN MOTOR-DRIVEN CUTTER, REAMER AND DRILL GRINDER

Wilmarth & Morman Co., 580 Canal St., Grand Rapids, Mich., has recently equipped its combination cutter, reamer and drill



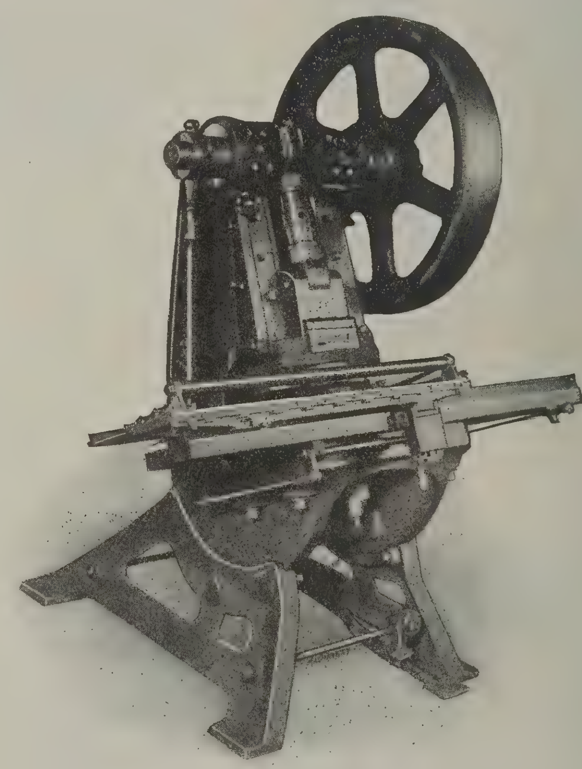
Wilmarth & Morman Motor-driven Combination Cutter, Reamer and Drill Grinder

grinder with a direct connected motor drive. The motor on this machine is one horsepower, and is made by the General Electric Co. to meet the special requirements of the present class of work. The controller for the motor is mounted on the column of the machine, and the power switch is located directly beneath the controller. The table and its slide are mounted on a knee, as shown in the illustration, so that it is possible to swivel the table around to enable grinding to be done on either side of a plain wheel, or to provide for the use of a cup-wheel.

The machine will grind face and side milling cutters up to 12 inches in diameter, straight or taper reamers up to 17 inches in length with flutes not over 11½ inches, angle milling cutters of any angle up to 8 inches, plain milling cutters of any type up to 8 inches, gear cutters up to 5½ inches, hobs up to 5½ inches, forming cutters of any length up to 5½ inches in diameter, and flutes of taps up to 11½ inches in length. The machine will take cylindrical or taper work up to 7¼ inches in diameter and 11½ inches in length. It has a maximum distance between centers of 17 inches, and a capacity for internal grinding up to 4 inches in depth by 10½ inch swing. The drill grinding attachment is the regular new Yankee non-calipering type, which provides for simply dropping the drill in the holder and grinding it. The capacity for drill grinding runs from No. 60 to ⅝ inch, from 3/32 to 1¼ inch, or from ⅛ inch to 2¼ inches.

STAGGER FEED SPACING TABLE FOR BLISS PRESSES

The E. W. Bliss Co., 5 Adams St., Brooklyn, N. Y., has recently developed and patented a stagger-feed spacing table for use in connection with inclinable single-crank and three-



Bliss Inclinable Press equipped with Stagger-feed Spacing Table

crank, double-action presses. This attachment is adapted for rapid, accurate feeding of decorated stock for bottle caps, covers, and similar work.

The table is moved by the operator after each stroke of the press and is locked by a cam-actuated stop which engages a rack on the table. The table is a light aluminum casting mounted on rollers. This construction allows the operator to cut an entire row of blanks without stopping the press. A handle bar is provided which is used to move the table and also, through eccentric pivots, to control the grippers. The sheet is first placed between the guides on the table and rests on a pair of preliminary stops which locate it for cutting the first row. A twist of the handle bar then closes the grippers, the preliminary stops are lifted clear by a knob at the right and the first row is cut. Subsequent rows are gaged by al-

lowing the sheet to drop against a straightedge at the back. All the operator has to do is to open the grippers, allow the sheet to fall, and close the grippers again.

A pair of scrap cutting dies is used to trim the sheet so that new gage points are made as each row is cut. The scrap is cut into small pieces, and scrap cutters are usually mounted on the same block as the die, to facilitate setting. The table is designed to handle standard sheets 20 inches wide by 28 inches long, and adjustment is provided to take sheets up to 30 inches long. The spacing rack for gaging is clamped over a T-slot and can be removed readily and different spacing racks attached. The speed of the press can range from 120 to 150 strokes per minute, depending on the size and character of the work.

THE CINCINNATI 36-INCH FROG AND SWITCH PLANER

The Cincinnati Planer Co., Cincinnati, O., has recently added to its line the 36-inch frog and switch planer illustrated in Figs. 1, 2 and 3. This machine has been constructed along lines which give it ample strength and rigidity for the heaviest classes of work. The bed is of the modern deep pattern, braced throughout by box girders, and is made with four

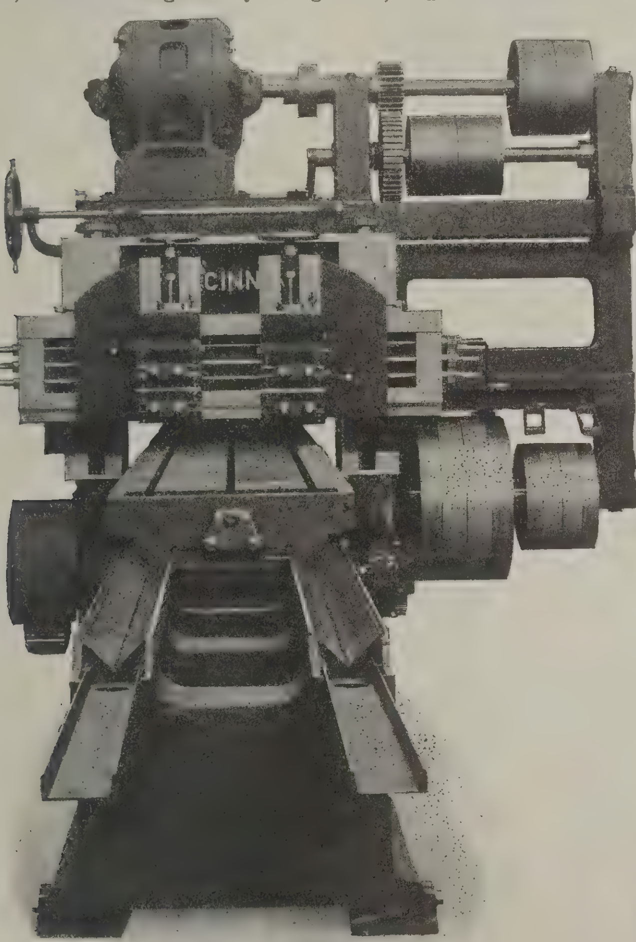


Fig. 1. Front View of Cincinnati 36-inch Frog and Switch Planer

walls between the housings where the greatest strain is developed. The vees are extra wide and are oiled by a forced lubrication system which maintains a film of oil between the table and bed at all times. The table is 32 inches in width, and has an inside bearing on the bed for its entire length, thus overcoming the pressure of heavy side cuts. Adjustable side gibs are provided on each side to prevent the table from lifting. The housings, which are of box form, have a 10-inch face and extend down to the floor. They are secured to the bed by bolts and dowel pins, and a tongue and groove 1½ inch deep by 5 inches wide. The cross-rail is 20 inches wide and has a deep ribbed box brace on the back to provide increased stiffness. In addition to the usual outside set of clamps, it is secured to the housings by an extra set of clamps on the inside; this design provides a very rigid form of construction. If desired, the cross-rail can be fastened to the housings by large dowel pins at various fixed heights. The rail screw has two long nuts in the saddle, thus reducing the strain on the threads when taking heavy side cuts and also insuring long life for both the screw and nut. The heads have automatic cross and vertical feeds, and are made right and

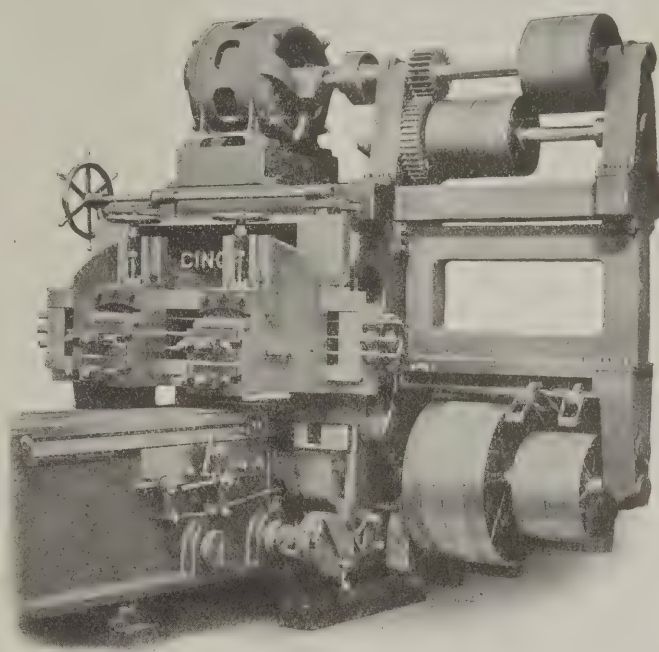

Fig. 2. Operating Side of Cincinnati Planer

left to bring them close together. The saddle and harp are made in one piece, without a swivel, and have a bearing of 25 inches on the rail. The countershaft is mounted on top of the housings and is driven by a 50 H. P. motor as shown, thus making the machine self-contained. A heavy cast-iron frame is fitted between the upper and lower bearings, and is

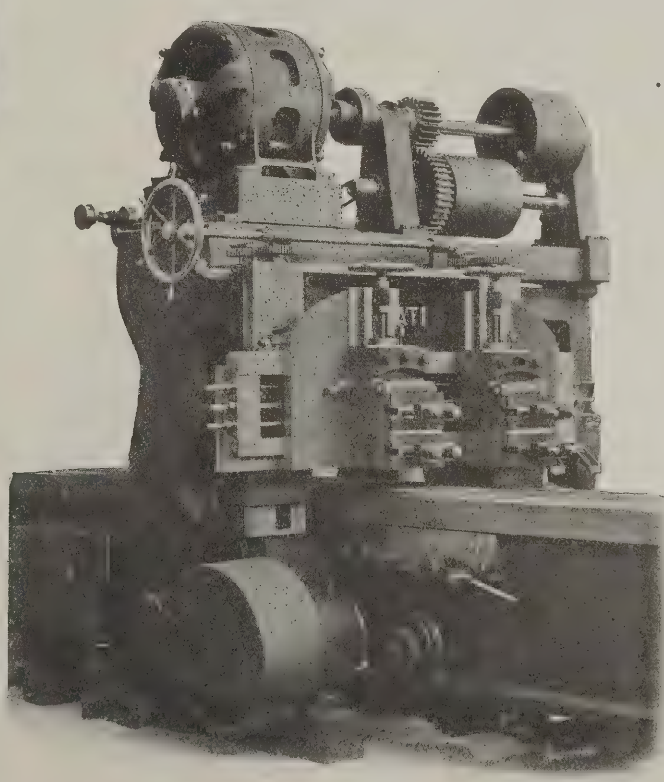

Fig. 3. Another View of Frog and Switch Planer

also fastened to the housings so that there can be no spring in the shafts or bearings when the machine is working on the heaviest cuts. The driving pulleys are 34 inches in diameter and are made of aluminum alloy, thus providing for a quick reverse on short strokes. The four-belt drive used on this planer provides ample power for the heaviest classes of work, and the shifting mechanism is provided with a safety locking de-

vice which prevents the table from starting, except at the will of the operator. Levers are so arranged that the machine can be operated from either side. The driving shafts are of unusually large diameter; they are made of special crucible steel. They are accurately ground and run in long bearings which are fitted solidly into the bed. The driving pulleys are so constructed that they only require oiling once in sixty days. The rack and gearing are made of solid crucible steel, to enable them to withstand heavy strains incident to frog and switch work; the bull wheel and rack are 12 inches in width and 1½ diametral pitch.

BLAKE & JOHNSON GANG SLITTING MACHINE

The Blake & Johnson Co., Waterbury, Conn., has brought out an improved gang slitter for cutting steel or other metals into strips. This machine, which is illustrated in Figs. 1 and 2, is so designed that the cutters can be changed in a minimum of time. The upper arbor is hinged on an intermediate shaft and is adjustable to or from the lower arbor, on an arc rather than a straight line. As the driven gear on the upper arbor revolves about the center of the driving gear, both gears remain in mesh regardless of the upper arbor's position. With this arrangement, it makes no difference whether the cutters have a diameter of 5¼ inches, as when new, or are reduced to the minimum diameter of 4½ inches, because the adjustment for changes in diameter can be made without introducing lost motion in the driving gears. The upper arbor is driven by a bronze gear on the intermediate shaft, which is in mesh with the steel gear on the lower arbor.

In order to change the gangs of cutters for slitting different widths, it is only necessary to remove two cap-screws at the foot of the outboard housing, slide the housing clear of the arbor ends, release a lock-pin and adjusting screw and swing the upper arbor up and away from the lower one (see Fig. 2). The ease with which cutters can be changed will be appreciated where different widths of stock are required.

The machine is driven by a sensitive clutch pulley, the clutch of which can be operated either from the front or rear of the machine, or from a considerable distance by means of a suitable rope connection. The clutch pulley is 16 inches in diameter and has a 4-inch face, and the power is transmitted through back-gears having a ratio of 4.2 to 1. All the bearings of the machine are bronze-bushed and the arbors are made of crucible steel. This slitter has a capacity for stock up to 6 inches wide and is especially adapted for slitting steel

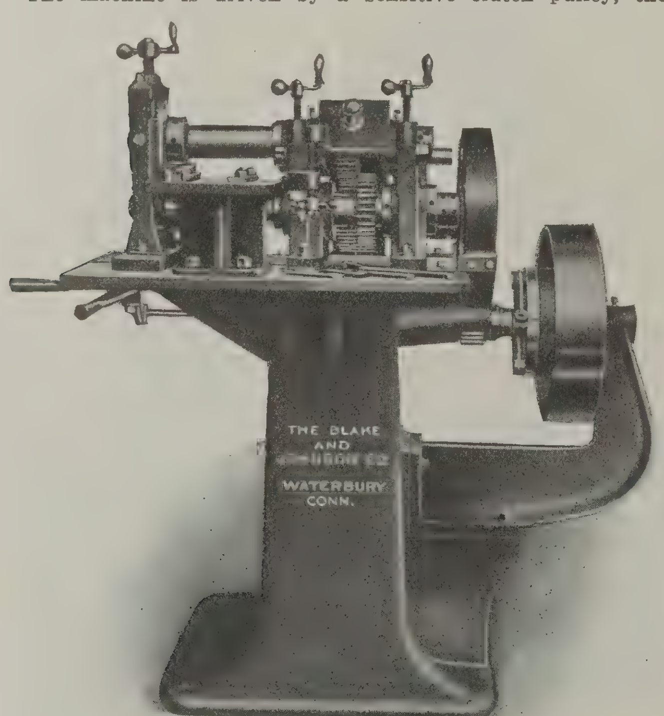

Fig. 1. Blake & Johnson Gang Slitting Machine

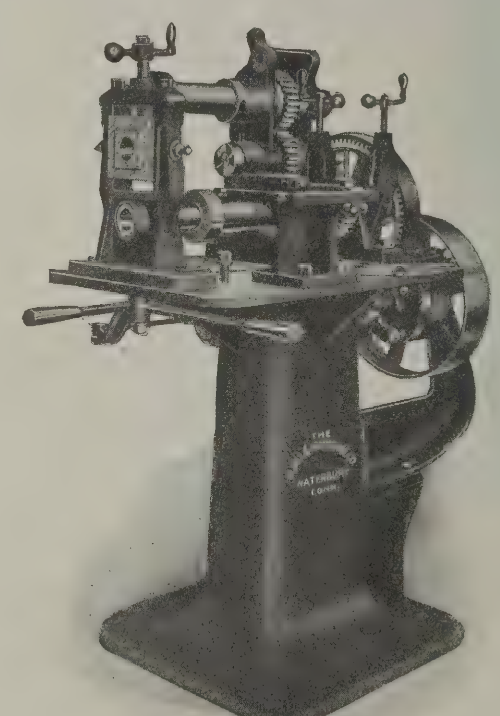

Fig. 2. Slitter with Housing moved back for changing Cutters

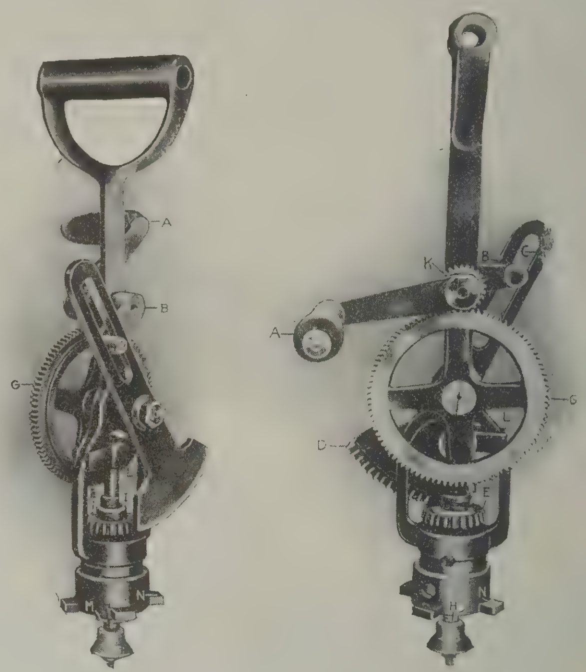
AUTOMATIC VALVE GRINDER

The valve grinder illustrated herewith is intended for grinding the valves of gasoline engines. This grinder gives a continuous cycle of operations, so that the valve is evenly ground and accurately seated. The valve is rotated in opposite directions in its seat and is progressively advanced periodically in one direction. First the valve is reciprocated on its seat a



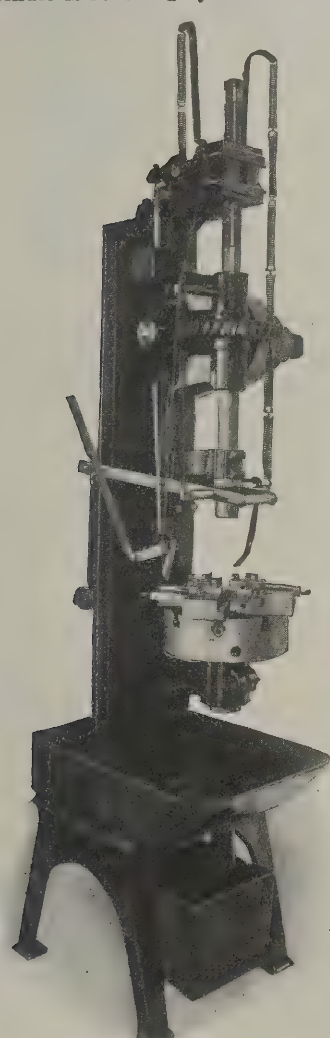
Specialty Machine Co.'s Hand-operated Valve Grinder

given number of times; it is then lifted, and when released by a suitable cam is automatically placed in a different angular position on the seat, after which it is automatically moved forward through a given angle and again reciprocated. The operation of this grinder is as follows: When the handle *A* is turned, crank *B*, which engages slot *C*, imparts an oscillating motion to segment *D*, which reciprocates the small pinion *E*. This pinion, through clutch *I*, transmits motion to the driving spindle *H*. At the same time, gear *G* is driven by a small pinion *K*. Located on the inside of gear *G* there is a cam which periodically comes under a roller mounted on carrier *L* and lifts clutch *I* from engagement. The clutch remains disengaged until pinion *E* is rotated through a given

arc, when the cam drops the clutch back into engagement. This movement effected by the cam also lifts the valve from its seat. Spring *M* engages the clutch at the proper time and insures a constant grinding pressure. The compression of this spring varies in accordance with the size of valves which are to be ground. The weight of the tool and downward pressure of the operator is carried by shoulder *N* which rests on the valve opening of the engine. This automatic valve grinder is being manufactured by the Specialty Machine Co., 95 Liberty St., New York.

BICKFORD UPRIGHT TAP-THREADING MACHINE

The Bickford Machine Co., Greenfield, Mass., has placed on the market a new machine for threading taps. This machine is an upright design, as the accompanying engraving shows. The taps are threaded by a die-head located below the spindle and supported by a foot projecting from the vertical column. The spindle rotates the tap blank being threaded, and, at the same time, is fed downward by a lead- or master-screw. The spindle is revolved by means of coarse-pitch worm-gearing having a ratio of about ten to one. The worm is carried by a horizontal shaft located near the top of the machine. This shaft is driven by a three-inch belt connecting with the cone pulley seen to the right of the worm-gear, and the latter transmits the motion to the spindle.



Bickford Tap-threading Machine

The lead-screw is in the form of a threaded shell. It is located on the upper end of the spindle and is engaged by half-nuts operating in a slide which forms part of the main column. The lower end of the spindle carries a holder for driving the tap blank, and the latter, when threaded, drops through the base of the machine. The spindle also carries (but does not revolve) a horizontal bar to which is attached, from above, pull-strings which return the spindle upward to its normal position when the half-nuts are released from the lead-screw. This disengagement of the half-nuts is effected by a trip which can be set to act just after the threaded tap drops from the holder.

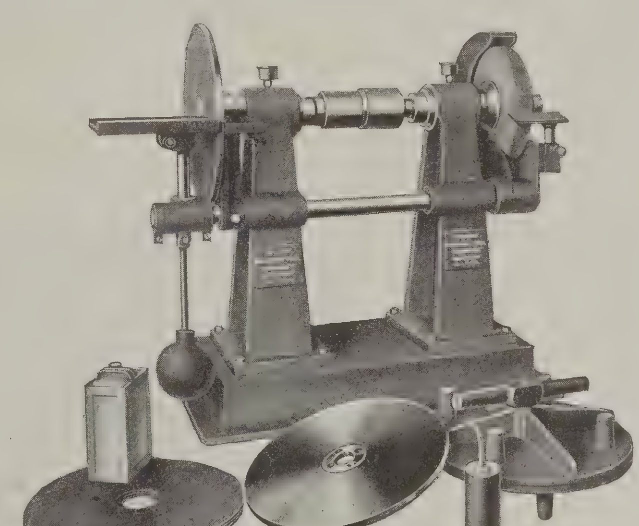
In operating the machine, the square shank of the tap blank is inserted in the holder at the lower end of the spindle, while the machine is running. The tap is held in position with one hand and the spindle is pulled down with the other (until the tap enters the die) by means of the short cross-handle seen in front of the spindle. The tap blank is then released and the lever on the left (which has a chain attached to its short arm) is pulled over, which engages the half-nuts with the lead-screw, thus causing the spindle to feed downward.

Lead-screws and half-nuts of different pitches are easily applied to the machine, and, if desired, they can be furnished with an increased lead to compensate for shrinkage in hardening the taps. A generous stream of oil is supplied to the work by a pump at the rear, which is driven from the countershaft. The lower bearing for the spindle can be removed easily, and, when this is detached, a much longer spindle travel is obtained. This feature adapts the machine to the threading of stay-bolt or other taps having long threads. The machine has a capacity for taps varying from one-half to two inches in diameter, and the same set of chasers can be used on any size tap having the same pitch of thread.

The company recommends the installation of two machines so that when threading large taps which require two cuts, the machines can be used in conjunction with each other. The threading die employed is a solid adjustable type having milled chasers. This die is efficient and produces accurate work. The total height of this machine is 8 feet 4 inches, and the weight about 1200 pounds.

SELLEW COMBINATION DISK GRINDER

The disk grinder shown in the accompanying engraving is built by the Sellew Machine Tool Co., Pawtucket, R. I. This is a combination grinder, one end having a 14- by 2-inch carborundum wheel for general work, and the other, a 20-inch disk wheel. The grinding wheel is enclosed by a substantial safety guard, carrying an adjustable support with rests so arranged as to enable the operator to work either on the front or side of the wheel. This equipment can be removed quickly for attaching buffing wheels, drums, etc. The spindle has a safety cap nut on its threaded end. The twenty-inch disk has a swinging table on the outer or finer side, which can be tilted for angular work and clamped in its tilted position. On the inner or coarse side of the disk, there is a stationary rest which can be used for supporting the work while taking roughing cuts or, if necessary, it can be swung down out of the way altogether. If desirable, both ends of the machine can be equipped either with disks and swinging tables or with grinding wheels.



Sellew Combination Disk Grinder

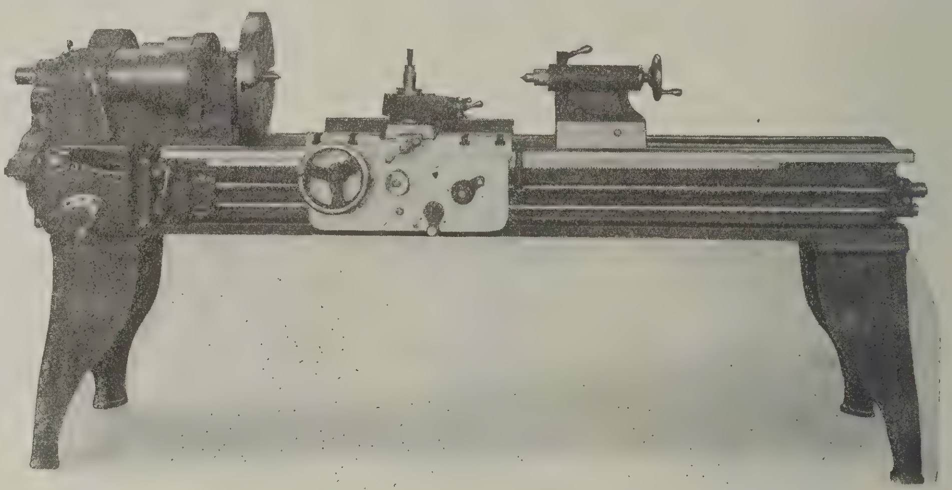
The spindle of this grinder was made exceptionally long in proportion to the diameter of the disk, to eliminate excessive wear of the journals and vibration. The length of the spindle over-all is 40 inches and the journals measure 2 by 7¼ inches. The journals are self-oiling and have ball bearings to take endwise thrusts. These bearings are protected by felt dust-guards. The spindle driving pulley is somewhat larger in diameter than the loose pulley, in order to relieve the tension of the belt when it is shifted to the loose pulley. The weight of the machine, complete with the necessary equipment, is 1600 pounds.

CONOVER-OVERKAMP QUICK CHANGE GEAR LATHES

The Conover-Overkamp Machine & Tool Co., Dayton, Ohio, is now manufacturing the quick change gear lathe shown herewith. This design is made in 14- and 16-inch sizes and with either a large three-step cone and friction double back-

gears, as shown in the illustration, or with a five-step cone and single back-gears. These machines can also be equipped either with a quick change gear box, as illustrated, an all-geared feed-box, or a standard belt feed-box and change-gears. Each of these boxes is an independent unit and they are interchangeable. This feature makes it possible to attach any one of these three units to the lathe at any time; that is, either a quick change gear box, a geared feed-box or a belt feed-box.

All gears in the boxes are steel and the bearings are bronze-bushed and can easily be renewed, in case of wear, without affecting the center distances or alignments. The boxes are fastened to the bed by four bolts and can easily be attached or removed. The change gear box, the geared feed-box, and the belt feed-box, are simple designs and there are no overhanging parts at the end of the lathe. The quick change gear box contains a driven shaft carrying a tumbler gear which can be engaged with any one of the eight cone gears. In constant mesh with the cone gears, there is an intermediate shaft provided with four gears, and a set of sliding gears can be engaged with any one of the intermediate gears by means of the lower lever seen at the front of the box. With this arrangement, thirty-two changes are obtained with but two operating levers and without removing or changing a single gear. A stud is provided on the reverse quadrant for compounding or for the introduction of special gears, so that special or metric threads can be cut with the standard lead-screw. The geared feed-box has four changes and is operated by one lever. The changes are obtained through sliding gears and positive clutches. The belt feed-box is equipped with a belt tightener.



Quick Change Gear Lathe built by Conover-Overkamp Machine & Tool Co.

These lathes can be furnished with standard legs, cabinet legs and also with short legs and oil pans. A taper attachment can be added at any time, as all carriages are planed and drilled for this purpose before the lathe is shipped.

NEW MACHINERY AND TOOLS NOTES

Precision Boring Head: Precision Tool Co., Lansing, Mich. A new precision boring tool for use in fine miller work and similar classes of service. This tool is equipped with an adjusting screw to adjust it for any size of radius work, the screw being provided with a micrometer attachment for securing any radius that is required.

Spiral Cutter Grinder: Sloan & Chace Mfg. Co., Newark, N. J. A spiral cutter grinder, semi-automatic in its action, which has an emery wheel four inches in diameter. The machine will grind an eight tooth 45 degree angle cutter in three minutes. The wheel spindle is fitted with S. K. F. ball bearings and the work is held between centers.

Mandrel Press: G. T. Eames Co., Kalamazoo, Mich. A mandrel press provided with a leverage system which multiplies the applied force by three hundred. This press is equipped with a square ram and is operated by a rack and pinion; it has a lock-nut that enables the ram to be clamped in any position while adjusting the work. These presses are made in a variety of lines and sizes.

A Group of Special Lathes: Whitcomb-Blaisdell Machine Tool Co., Worcester, Mass. A special manufacturing lathe, designed with the jack shaft under the bed so that the machines can be grouped together and arranged for any desired speed. The driving pulley is loosely mounted on the spindle and is engaged by means of a friction clutch; the lathe headstock is cored out to permit the passage of the driving belt.

Metal Cutting Machine: Racine Tool & Machine Co., Racine Junction, Wis. A new type of metal cutting machine equipped with a three speed attachment designed to give speeds of 60, 90 and 125 R. P. M. respectively, when cutting unannealed tool steel, annealed high-speed steel and mild steel. The general construction of the machine follows the lines which are now generally recognized as standard for equipments of this type.

High-Speed Hacksaw Machine: E. C. Atkins & Co., Indianapolis, Ind. A high-speed hacksaw machine known as the No. 7 "Kwik Kut," equipped with a swivel vise and independent motor which has a speed range of 550-1100 R. P. M., and drives by means of a Morse chain running over hardened steel gears. The machine is provided with the most modern type of lubrication system and method of raising the saw on the idle or return stroke.

Electric Drilling Machine: Van Dorn & Dutton Co., Cleveland, O. An electrically operated drilling and reaming machine which has a drilling capacity of one-half inch in steel and one inch in wood, and a reaming capacity of 7/16 inch. The machine is 14 inches high from the top of the handle to the bottom of the chuck, and weighs 17 pounds. It is designed to operate at a speed of 700 R. P. M. and can be furnished for connection with either 110 or 220 volt lines.

Multiple Drilling Machine: Taylor & Fenn Co., Hartford, Conn. A machine equipped with a multiple head that is built with from two to fourteen spindles. The position of these spindles is not adjustable, so that special heads are required for each class of multiple drilling that is to be done. The spindles are gear-driven, and as the gear ratio is arranged to provide the proper speed for various sizes of drills, it is necessary to specify the size of drills that are to be used.

Double Arbor Buffing and Polishing Machine: Excelsior Tool & Machine Co., East St. Louis, Ill. A special design of buffing and polishing machine which has two independent spindles, giving a combination of handiness of operation, simplicity, and large capacity. The entire machine is enclosed by dust-proof covers and has a solid bracket for attaching the dust hood. The machine is designed to run at a speed of 300 R. P. M., although this figure may be varied slightly to meet the requirements of individual classes of work.

Revolution Counter: American Ever Ready Co., 304 Hudson St., N. Y. City. A new type of revolution counter that is shaped somewhat like a revolver and of about the same size. The starting and stopping of the counting mechanism of this device are not dependent upon the amount of pressure applied in holding the counter against the revolving spindle. The counting mechanism is started and stopped by operating a trigger, and the recorder indicates in the forward direction regardless of the direction of rotation of the shaft.

Belt Surface Grinder: Peerless Surface Machine Co., Newark, N. J. A line of belt surface grinders of both vertical and horizontal types, and of different sizes for a variety of classes of work. These machines are provided with an endless belt upon which the abrasive material is mounted, and a work table that can be swung to any desired angle. The bearings in which the spindles of the belt pulleys run are provided with boxes of the sliding type, which enables any stretch in the belt to be taken up. A dust collector is arranged to catch the metal dust which is removed from the work.

Plain Radial Drilling Machines: Dreses Machine Tool Co., Cincinnati, O. These machines are of the 3- and 3½-foot size, and are similar in construction to the 5-, 6-, and 7-foot sizes illustrated in November, 1911. They are designed for the use of high-speed drills, are convenient to operate and substantially built. The outer column swings on a fixed inner column extending to the top, and there is a third bearing in the middle which greatly increases the strength and rigidity. The arm is of box, parabolic shape and the lower rib is double-webbed, thus giving great resistance to bending and torsional strains. The head has long and wide bearings on the face of the arm, and, in addition, a third bearing at the rear. This third bearing gives extra support to the head, prevents bending the rear shaft, reduces the wear of the bevel gears and bearings and distributes the torsional strain over the entire arm. The spindle has twenty-one speeds, runs in phosphor-bronze bearings and is driven by two keys. The driving gear of the spindle rests and revolves on a ball bearing, which is said

to effect a power saving of 15 per cent. The feed is all-geared and there are eight changes which can be varied while drilling, by a handle located on the head. There is an automatic stop and depth gage; a quick-return having four handles, either of which can be used for engaging or disengaging the feed; and a tapping, starting and stopping mechanism of the frictional type, operated by a conveniently located lever.

* * *

BORING MORTAR CARRIAGES

At the Builders' Iron Foundry, Providence, R. I., some interesting work is going through in connection with the making of disappearing carriages for mortars for the U. S. Government. These mortars are of the 12-inch size, model 1896—M—III, and will be used for coast defense. One of the trunnion castings is shown in Fig. 1. This casting weighs 5620 pounds,

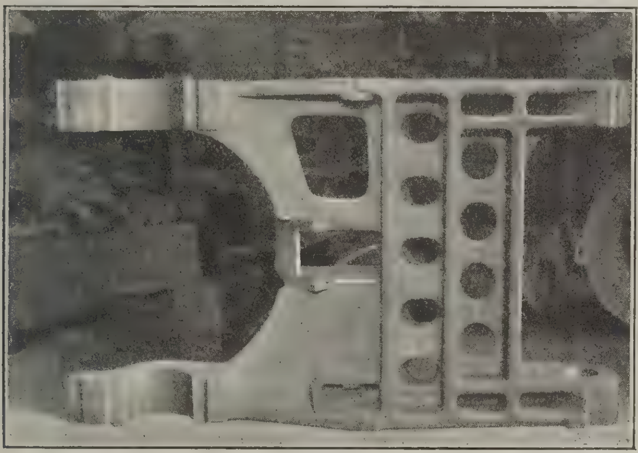


Fig. 1. Disappearing Mortar Carriage Casting being bored in Fig. 2

and the boring operations on it well illustrate the general character of the work.

This work consists in the boring of the large trunnion holes at one end, the fulcrum pin holes at the opposite end, and miscellaneous smaller holes between the two ends to receive the intermediate and elevating shafts. In doing this work a universal boring machine is used, as shown in Fig. 2. In order to facilitate the handling of the work upon this machine a special table was made to assist in supporting the work while being operated on. This will be observed in place on the machine beneath the casting. Before the casting is bored, however, the trunnion ends are milled and fitted with the bearing caps. This being done, the casting is mounted on a fixture and the fixture supported on the machine in position for boring the trunnion holes, which are finished to a size slightly over 13 inches. It is important that this dimension be very accurate. It will be observed that the casting is too large to be supported wholly on the table of the machine, and it is necessary to support the outer end upon jacks which may be seen in Fig. 2. This part of the work being done, the casting is reversed, and, by supporting a test-bar in bearings which have been provided in the trunnion end of the fixture, a convenient means is afforded for taking measurements when boring the fulcrum pin holes. This is the operation shown being done in Fig. 2. After both ends have been bored, the several smaller bearing holes for the intermediate and elevating shafts are bored at intermediate positions between the ends of the casting.

The work is under the direction of a government inspector, and the limits allowed are extremely close in regard to diameters of holes, distances between holes, and parallelism.

* * *

TO DISTINGUISH BRASSES BY COLOR

The composition of the brasses (copper and zinc alloys) may be readily determined, approximately, by the color. The method gives a brass founder a simple and rapid means for ascertaining what his brass contains. The following shows the color of the various percentages of copper and zinc:

When the brass contains 5 per cent of zinc, it has a red color scarcely differing from that of pure copper. When 10 per cent of zinc is present, the mixture has a true bronze color. With 15 per cent of zinc, the brass has a light orange shade. When the amount of zinc reaches 20 per cent the color of the mixture is greenish-yellow and is known as "green brass." With 25 per cent zinc, the color is practically that of the 20 per cent mixture so that this, too, is a "green brass." Brass with 30 per cent zinc has the true, yellow brass color. The same is found with 35 per cent of zinc, but at about this point the yellow color begins to disappear, for at 40 per cent zinc a reddish yellow color is found. Brass, therefore, that has a reddish-yellow shade will always contain more than 35 per cent zinc. The "dead line" seems to be about 38 per cent zinc, for at this percentage, the transition from the real yellow to the reddish-yellow begins.

When the zinc is increased to 45 per cent, the color of the brass is a rich golden shade and, strictly speaking, it may be called "orange." The mixture containing 50 per cent zinc has also a golden shade, but even richer than 45 per cent zinc alloy. At 55 per cent zinc, the color resembles that of 14-karat gold. When 60 per cent of zinc is reached, the brass has a yellowish white shade, and as the quantity increases, the color becomes white and finally gray.

It becomes possible, then, to make an approximate determination of the composition of a brass by the color. If it is very soft and red or orange color, then the amount of zinc is from 10 per cent to 15 per cent. If greenish-yellow, the quantity of zinc ranges from 20 per cent to 25 per cent. The true brass color is found when the zinc amounts to from 30 per cent to about 38 per cent. If, however, it is found that the brass is hard and has an orange yellow color, then the zinc must be present in an amount greater than 38 per cent. To cite an instance of this kind, a concern may be purchasing yellow-brass ingot. If, upon cutting or filing it, the color is found to be orange, then the zinc in it is excessive and may run from 40 per cent to 50 per cent.

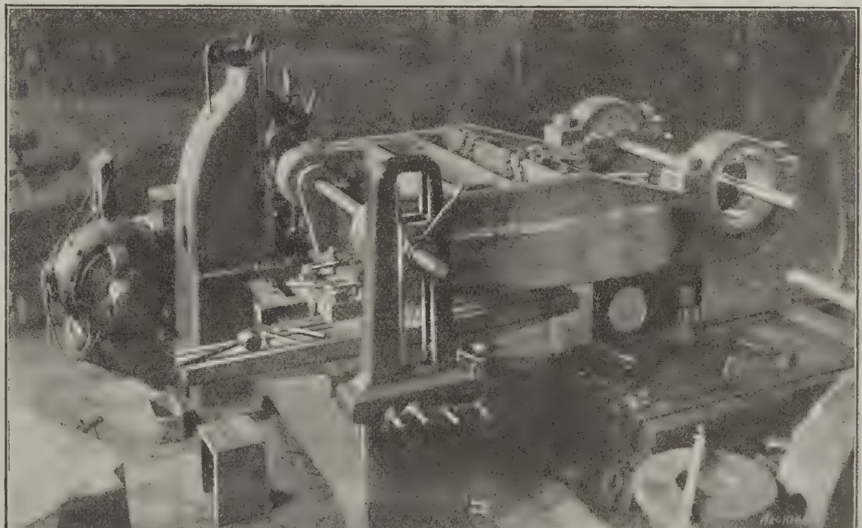

Fig. 2. Boring a Disappearing Mortar Carriage Casting on a Universal Boring Machine

In comparing the color of the brasses, a highly polished surface is not as suitable as a dead one for the reason that false reflections are apt to deceive the observer. A surface that has been filed or ground is preferable, and in order to avoid tarnishing the metal should be freshly cut when a comparison is to be made.—*Brass World.*

* * *

The following method for preventing short-paid postage on letters to foreign countries has been adopted by a large firm having a considerable amount of foreign correspondence: Different-colored envelopes are used by the stenographers when addressing letters to foreign countries. The stamping clerk first of all segregates the letters according to the color of the envelopes and then stamps them as required. Mistakes become very rare under this system, and the simplicity of the system recommends it for use.

THE NATIONAL MACHINE TOOL BUILDERS' ASSOCIATION CONVENTION

The eleventh annual convention of the National Machine Tool Builders' Association was held at the Hotel Astor, Wednesday, Thursday and Friday, October 16 to 18. The meeting was called to order at the morning session on October 16 by the president, E. P. Bullard, Jr., who referred to the work of the association in a brief address. The remainder of the session was given over to the reports of committees. The membership committee reported applications for membership from the following firms:

Beaman & Smith Co., Providence, R. I.
Blake & Johnson Co., Waterbury, Conn.
Turner Machine Co., Danbury, Conn.
Union Twist Drill Co., Athol, Mass.
Waterbury Farrel Foundry & Machine Co., Waterbury, Conn.
Zeh & Hahnemann Co., Newark, N. J.

These firms were elected to membership, making the total number of members 188. Reports were also submitted by the committee on standardization, foreign relations, patents, and investigation of cutting tools. A resolution was passed, after some discussion, making a change in the membership fee—graduating it according to the capital and surplus of the respective members.

During the afternoon session, October 16, and the morning session, October 17, the following papers were read:

"Export Trade," by W. A. Viall, of the Brown & Sharpe Mfg. Co., Providence, R. I. (See abstract in this number.)

"The Use of an Association Catalogue in the Development of Foreign Markets," by Stanley H. Bullard, of the Bullard Machine Tool Co., Bridgeport, Conn.

"How United States Patents might be made of Greater Value to Patentees," by Samuel W. Banning of Banning & Banning, patent attorneys, Chicago, Ill.

"Tariff Legislation and its Influence on the Machine Tool Trade," by C. Wood Walter, of the Cincinnati Milling Machine Co., Cincinnati, Ohio.

"How could the Association be benefited by the Formation of a Mechanical Section?" by E. J. Kearney of the Kearney & Trecker Co., Milwaukee, Wis. (See abstract in this number.)

The sessions on the afternoon of October 17 and the morning of October 18 were devoted to committee meetings on lathes, sensitive drilling machines, boring machines, gear cutting machines, grinding machines, hand screw machines, planing machines, radial drilling machines, milling machines, shaping machines, vertical drilling machines, and turret lathes.

It was decided to hold the next spring meeting in New York City. The following officers were elected for the coming year: president, E. P. Bullard, Jr., of the Bullard Machine Tool Co., Bridgeport, Conn.; vice-president, A. T. Barnes, of the W. F. & John Barnes Co., Rockford, Ill.; second vice-president, R. K. LeBlond, of the R. K. LeBlond Machine Tool Co., Cincinnati, Ohio; treasurer, A. E. Newton, of the Reed-Prentice Co., Worcester, Mass.; and secretary, C. L. Taylor, of the Taylor & Fenn Co., Hartford, Conn.

The Association Catalogue

The paper by Mr. S. H. Bullard aroused considerable interest on account of the novelty of the idea presented, and was followed by an animated discussion. The idea proposed is, briefly, that the association should publish a catalogue for distribution mainly in foreign countries, in which the product of every member should be represented, this catalogue to be printed in English, German, French and Spanish. Apparently most of the members present favored the idea. A committee was appointed to further work out the details, and this committee reported at the last session, October 18, the report being to the effect that a permanent committee should be appointed and that the details of the issuing of a catalogue as proposed should be taken up by letter ballot with the members. At the same meeting a special committee was decided upon to report to the association at its next meeting on the question relating to the formation of a mechanical section raised by Mr. Kearney's paper on the subject.

Patents and Patent Legislation

The paper on patents and patent legislation, by Mr. S. W. Banning, contained a review of the Oldfield bill now before Congress, which is designed to eliminate certain alleged abuses which have grown up during the old patent law. The speaker referred to the main features of the bill (see MACHINERY, July, 1912, "Proposed Changes in Patent Laws"), and particularly gave attention to the compulsory license clause against which he presented an argument. The section of the bill referring to restrictions with respect to the resale or use of patented machines after the title to such machines has passed from the manufacturer, was also referred to, as well as the conditions where contributory infringement is claimed on account of the use of accessories with the patented machine which are not secured from the seller of such machine. The stand taken by the speaker was that when the restriction is one that relates exclusively to the patented invention, it should be amenable to the remedy provided for enforcement of the inventor's rights in an infringement suit; but when the restriction is one that relates to supplies of a general nature, the question is one outside the realm of patent infringement and one that should simply be decided as a question of breach of contract, the validity of the contract to be decided in ordinary court proceedings. It was pointed out that under present practice the patent may be used as a weapon to enforce control of the use and sale of articles that are not even accessories to the machine patented and which are wholly unrelated to its use. As an example, the patentee of an adding machine may sell it with the restriction that its use is conditional upon the purchase from the same source of all typewriters required by the user, and under penalty of suit for infringement of the adding machine patent. In this way, the present law would permit the patentee to extend his monopoly to cover a device upon which he has no patent and which bears no relation to the invention actually protected. Reference was also made to some questions not included in the Oldfield bill.

Under the present practice the inventor is required to append to his specification one or more claims which point out and limit the invention, and which are intended by their language to distinguish it from all prior inventions. The invention is considered as a concrete embodiment of certain mechanical parts or elements, and the claim is restricted to this physical combination. The real invention, however, may go a great deal deeper than this, and in the case of basic inventions it is the underlying principles and not the mechanical embodiment which is of value and importance; but under present practice, inventions of this kind are the more difficult to adequately protect. Minor improvements are easily claimed in mechanical language, even when they are merely new mechanical embodiments of old basic ideas.

The speaker advocated that the inventors should be allowed to claim the functional co-relation of the parts in such a way as to cover every physical embodiment of the same fundamental principle. In this respect, the German practice is quite the reverse of the American practice. In Germany, the claim is directed to the basic functions of the elements involved, and this the speaker considered ought to be the case also under our patent laws. Under the present practice, the unnecessary strictness in claiming the invention, and the oftentimes ill-advised liberality of the courts in construing the claims, renders it extremely difficult to determine the rights of the patentee.

* * *

AMERICAN MACHINIST'S THEATER PARTY

The *American Machinist* followed its custom of some years standing by entertaining a theater party of several hundred machine tool builders, mechanical engineers and representative men in metal manufacturing lines, during the meeting of the National Machine Tool Builders Association in New York. The party saw the French comedy "Oh, Oh, Delphine!" played at the Knickerbocker Theater, Thursday evening, October 17, and was highly entertained by the spicy witticisms and catchy songs of this brilliant hit of the season.

* * *

The *Boletin de l'Industrie Minerale* states that aluminum wire is being extensively used in Europe for electric transmission lines, on account of the saving in first cost. The initial cost of an aluminum line is about 25 per cent less than an equivalent copper line, all items considered.

MACHINERY'S 1912 OUTING

MACHINERY'S tenth annual outing for machine tool builders, dealers and others connected with the machine tool industry, including many superintendents of manufacturing plants, took place on October 19.

MACHINERY'S steamer left the foot of East Twenty-fourth St. at 11 A. M., stopping first at the Brooklyn Navy Yard, the most important naval station in the United States, where Uncle Sam's new super-dreadnought, the 27,000-ton battleship *New York* is now under construction. The keel was laid in September, 1911, and she will be launched before this item is read. The Commandant and his aide had been suddenly ordered to Washington the night before, and through some oversight the arrangements made for the entertainment of the party were not carried out; but opportunity was afforded to inspect the yard and go aboard the battleships *Utah*, *Florida* and *Connecticut*.

Luncheon was served while at the Navy Yard, and immediately afterwards the steamer started up the East River and around Manhattan Island, passing through the Harlem River and shooting some fourteen bridges that span it, returning to the foot of East Twenty-fourth St. on time. The steamer was the largest that ever passed through the Harlem River, and it was a close call getting through High Bridge.

An unexpected feature of the outing which was highly enjoyed by the friends of Mr. Charles E. Hildreth, for some years secretary of the National Machine Tool Builders Association, was the presentation to him of a cake well covered with candles, in honor of his birthday, which happened to fall on October 19. A song especially written for the occasion was sung with gusto, and Mr. Hildreth responded feelingly.

MACHINERY'S outing was started ten years ago with a tally-ho ride given to twenty-one manufacturers and others present at the convention in New York at that time, and the attendance has now increased so that between five and six hundred representative men in the machinery industry meet each year to renew and extend their acquaintance and to spend a few social hours on that occasion.

* * *

PRICE SHEETS FOR SALESMEN

Loose-sheet price books have come into common use by machinery salesmen in the past few years. The page most used is of thin paper printed on one side only, cut to the standard, 4 inches wide and 7½ inches long, with three holes punched on three-inch centers, and with round corners. A sample page was shown in the April, 1912 number of MACHINERY on page 593, engineering edition. A well-known western machinery dealer is establishing among machine tool manufacturers for the use of their salesmen similar sheets printed on both sides and made of light weight tag stock, that is, white filled linen, which, of course, is much stronger and more durable than the thin paper commonly used. These sheets carry illustrations of machines on one side and the specifications on the other. The texture of the stock being coarse, it is advisable to illustrate with wood cuts or coarse screen half-tones, the illustrations being used simply to identify the machines and not to show details of construction clearly.

* * *

Thin steel saws for slotting heads of machine screws and bolts are tools which require frequent renewal. The work is very destructive and, ordinarily, the tools do not last long. However, one of these slitting saws, made of "Ark" high-speed steel, recently slotted 477,000 stove bolts before giving out.

NEW YORK ELECTRICAL EXPOSITION

The sixth annual electrical exposition, held in the Grand Central Palace, New York City, October 9 to 19, included a variety of interesting applications of electricity. The majority of the exhibits were of a nature to interest non-technical visitors, as they consisted of electrical devices used for household and office purposes. The exposition was opened with a luncheon in honor of Thomas A. Edison, commemorating the completion of thirty years of Edison service in New York City, given by the New York Edison Co., October 9. Mr. John W. Lieb, Jr., general manager of the New York Edison Co., related how the industry has grown since the opening of the historic Pearl St. plant, September 4, 1882. Electrical plants thoughout the country are capitalized at $2,500,000,000, having an annual capacity of 12,000,000,000 K. W., and gross earnings of $4,000,000,000.

The exhibit of the New York Edison Co. showed the wonderful development in the application of electricity which has taken place in the past decade. This fact will be readily brought out by touching upon the statistics presented by this company's commercial engineering department. Without entering into detail, an idea of this development may be gained from the fact that in 1899 the total horsepower of the motors connected to the Edison Co.'s system in New York City was 34,457, while in 1911 this figure had increased to 312,863. This is but one of the increases in consumption of electric power which have taken place, and it will be evident that to keep pace with such an increase of power consumption corresponding increases in generating equipment were necessary. The developments which have been made along this line are clearly set forth by models of the old Edison station on Pearl St., N. Y. City, which was built in 1882, and the Waterside stations which are carrying the load at the present time. These models are constructed on a scale of one inch to two feet, and show the complete plants, together with the arrangement of the equipment. The old "Jumbo" generators of the first Edison station in New York, which were built by Armington & Simms, Providence, R. I., and placed in operation September 4, 1882, were run under the following conditions: rated capacity, 126 K. W.; capacity in 16-candlepower lamps, 1000; square feet of floor space occupied, 122.5; R. P. M., 350; weight of generating set in pounds per K. W., 488; K. W. per square foot of floor space occupied, 1.03. The present type of Curtiss turbine generators were built by the General Electric Co., Schenectady, N. Y., to operate under the following conditions: rated capacity, 20,000 K. W.; capacity in 16 candlepower lamps, 1,000,000; square feet of floor space occupied, 297; R. P. M., 750; weight in pounds per K. W., 42; K. W. per square foot of floor space covered, 67.34.

Another particularly interesting exhibit is that of the Electrical Testing Laboratories of New York City. Among the apparatus shown, there was a series of twenty-seven electric meters which cover a range of design from the old-fashioned electrolytic type, which was the first used in New York City, up to the most modern type of instrument. In this connection it may be of interest to mention that the method of measuring current with the old electrolytic type consisted of shunting a part of the current through a cell; the amount of current passed was then measured by the weight of metal deposited from the solution. The Electrical Testing Laboratories have one of the original balances which were used to weigh the metal deposited in this way.

One of the interesting features of the exposition was the exhibit of the American Museum of Safety. A large number of wax models of different parts of the human body affected by a variety of vocational diseases were shown. This is a subject which has not received much attention in this country, but which has been studied in detail in Germany. Dr. Wm. H. Tolman, director of the American Museum of Safety, has recently been in Germany making a study of the results of investigations of this subject which have been made there, and the models exhibited were brought back by him from Germany. It is the intention of the American Museum of Safety to issue circulars at a later date showing the causes of such vocational diseases and the means of prevention.

DOGS AND DRIVERS

A review article was published in the October number, engineering edition, illustrating a large number of dogs and drivers for lathe and milling machine work held on centers. Unfortunately, a description of the meritorious safety lathe dog illustrated in two styles in Figs. 1 and 2, which is made by J. H. Williams & Co., Brooklyn, was omitted. In this lathe dog, the square-head set-screw so dangerous to the workman's hands and arms, is displaced by square socket set-screws always lying flush with the surface of the screw hub or below it. Inasmuch as the set-screws do not project above the surface, they cannot catch the workman's sleeve or other parts of his clothing and thus cause injuries.

Figs. 1 and 2. J. H. Williams & Co.'s Safety Lathe Dogs

This lathe dog is essentially the same in design as the form used in the works of the National Tube Co., and illustrated in the April, 1911, number of MACHINERY. A feature of the design of the drop forged dog is the reinforcement at each side of the screw hub made to strengthen it at a critical point and to eliminate the part of the boss which would project if the lines were the same as on the square-head set-screw type. These safety dogs are made in the same sizes as the regular square-head set-screw type dogs.

Another dog worthy of notice which is especially adapted for milling taper work, spiral taper reamers and other taper parts held on centers, is the Hill compensating dog made by the Ready Tool Co., of Bridgeport, Conn., and shown in Fig. 3. Features of this dog are a forked driver mounted on the spindle or faceplate and a dog having a tail with a ball-shaped part engaging the fork of the driver. The point of application of the forked driver on the ball is in approximately the same plane as the end of the piece being indexed. The object of this is to eliminate the irregularity of action in indexing tapered work that inevitably follows the use of the ordinary bent tail dog when engaged with an ordinary driver, and arises from the sliding of the taper tail of the dog in and out of the slot and the necessary looseness of engagement of the tail in the slot.

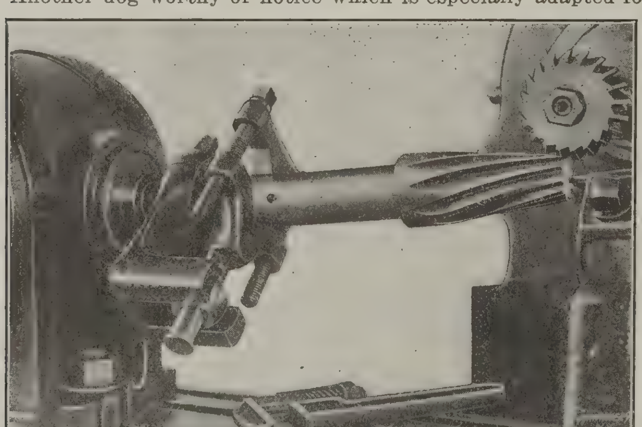

Fig. 3. Ready Tool Co.'s Milling Machine Dog

PERSONALS

Frank Koester, consulting engineer, has moved his office from 115 Broadway to larger quarters at 50 Church St. (Hudson Terminal Building), New York.

F. Mandon, manager of Fenwick, Freres & Co., Paris, France, is making a short visit to American machine tool building centers in the interests of his company.

E. G. Buckwell, secretary and manager of sales of the Cleveland Twist Drill Co., Cleveland, Ohio, sailed on the *Carmania* October 5, for a two-months' business trip abroad.

V. Brockbank, a British contributor to MACHINERY, has come to America and joined the National Twist Drill & Tool Co., Detroit, Mich., in the capacity of assistant superintendent.

E. J. Lees of the Lees-Bradner Co., Cleveland, Ohio, maker of gear hobbing machines, sailed for Europe October 1, on the *Mauretania*, for a five or six weeks' business trip in England and France in the interests of his company.

D. O. Barrett, superintendent for the past year-and-a-half of the Manitoba Engines Ltd., Brandon, Manitoba, and an occasional contributor to MACHINERY, has resigned to take charge of the experimental work of the Heer Engine Co., Portsmouth, Ohio.

H. W. Kreuzburg, president of the Champion Tool Works Co., Cincinnati, Ohio, who sailed for Europe May 25, returned early in October, having made an extended tour of British and Continental manufacturing centers in the interests of his company.

Ralph E. Flanders, advertising manager of the Fellows Gear Shaper Co., Springfield, Vt., has resigned to become manager of the Fay automatic lathe department of the Jones & Lamson Machine Co., Springfield, Vt., and also manager of the company's advertising.

Howard G. Carter will have charge of the equipment of the new $300,000 high school building in Hamilton, O. The school will have a completely equipped technical department including a machine shop, forge shop, foundry, pattern shop, stockroom, bench room and drafting-room.

Louis M. Pawlett has recently left the Locomobile Company of America, where he held the position of executive engineer, to enter upon a consulting practice in motor transportation engineering. For this purpose, Mr. Pawlett has opened offices in the new building of the U. S. Rubber Co., 1786 Broadway, N. Y.

John S. Myers, known to readers of MACHINERY as an occasional contributor of articles on machine design and other subjects, has resigned his position with the American Engineering Co. (successor to the Williamson Bros. Co. and the American Ship Windlass Co.) to go with the Southwark Foundry & Machine Co., Philadelphia, Pa.

J. McA. Duncan has been appointed district manager of the Westinghouse Electric & Mfg. Co. for the Pittsburg district, in place of Mr. W. F. Fowler, resigned. Mr. Duncan has been employed by the Westinghouse Electric & Mfg. Co. about twenty-five years, and is one of the group of eight men taken over from the Union Switch Signal Co., then located in Garrison Alley, Pittsburg, to form the electric company, which was first established at the same place.

* * *

OBITUARIES

William H. Corbin, vice-president of the Joseph Dixon Crucible Co., Jersey City, N. J., died at his country home in Sullivan Co., N. Y., September 25, aged sixty-one years.

Stephen Holman, founder of the Holyoke Machine Co. of Worcester and Holyoke, Mass., died at his home in Swampscott, October 13, aged ninety-two years. Aside from his machine building industries, Mr. Holman was also for many years in the cotton industry, and was a leader in the National Association of Cotton Manufacturers. He was a graduate of Williams College.

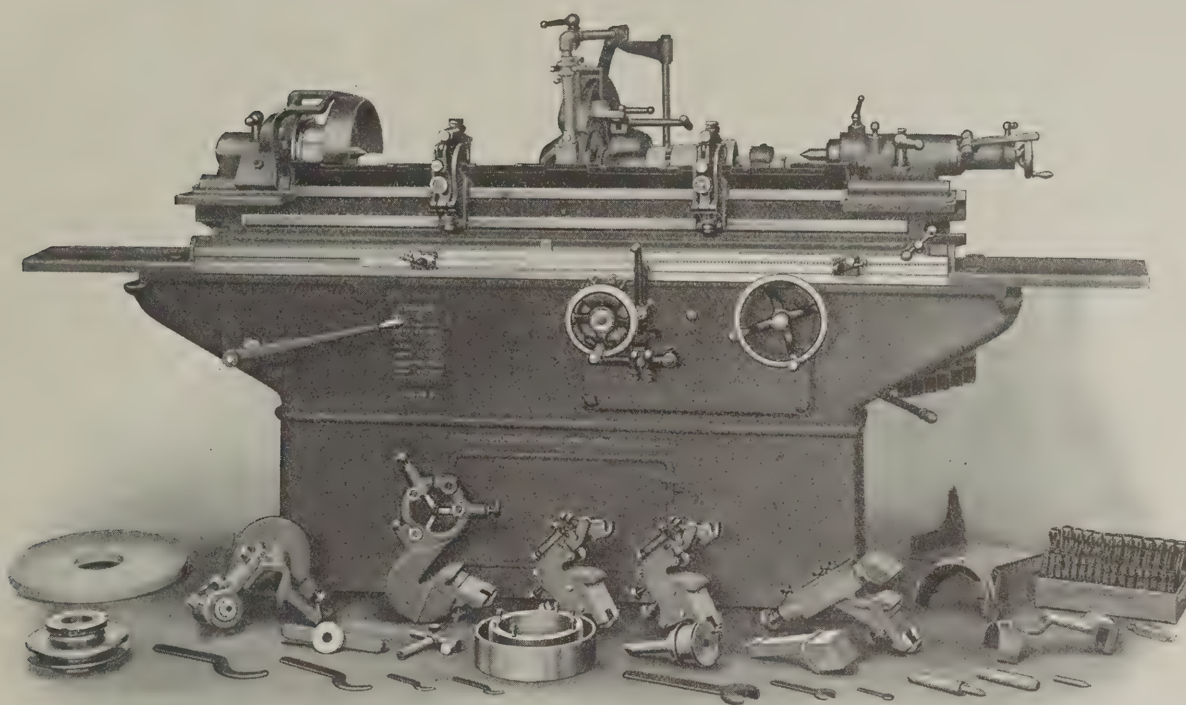
Horace Inman, president of the Inman Mfg. Co., Amsterdam, N. Y., died October 16, aged seventy-three years. Mr. Inman was widely known because of his invention of automatic and semi-automatic paper box machinery. He was one of the three mechanics who received a diploma at the World's Columbian Exposition at Chicago, the other two being Ambrose Swasey and Edwin Reynolds.

* * *

The replacing of forty-four consolidation engines by twenty-five Mallet compound locomotives on the Hinton Division of the Chesapeake and Ohio Railroad, has resulted, it is stated, in a saving of 37.55 per cent of the cost of handling the freight traffic on this division. As the Mallet locomotives are more costly than were the consolidation locomotives, this saving is reduced by the amount of the interest and depreciation of the excess cost of the Mallet engines. Nevertheless, there appears to be a clear saving of more than 30 per cent of the total cost of handling the freight traffic.

No. 14 Plain Grinding Machine

Built in two sizes, 10" x 30" and 10" x 48"



If your work calls for a machine to grind spindles, shafts, rolls, etc., up to the sizes above, the advantages of this one are worth considering.

The rigidity of all parts enables heavy cuts to be taken at fast speeds and coarse feeds. An automatic cross feed and universal back rests insure accurate duplicate pieces. The work speeds and table feeds are independent of one another so a correct feed is available for any speed. Simplicity of all parts makes the machine easy to operate. The few handwheels and levers on the front are handy for the operator and do not come in his way when changing or gauging work.

Folding guards on the 10"x30" size

economize greatly on floor space required—a factor of considerable importance in the average shop.

Write for a special circular.

BROWN & SHARPE MFG. COMPANY

PROVIDENCE, R. I., U. S. A.

A NEW METHOD OF REVEALING SEGREGATION IN STEEL INGOTS

The description given by Sir Robert Hadfield in a paper on the above subject, presented before the September, 1912, meeting of the Iron and Steel Institute, is closely related to the text of his paper describing his methods of producing sound ingots, which was also presented at this meeting. The object of the present paper is to describe a method of studying the conditions under which segregation takes place with the view of arriving at some method of eliminating, or at least checking, the formation of segregated sections.

Segregation may be briefly described as the tendency for objectionable impurities in steel—particularly sulphur and phosphorus—to be concentrated at the center of the ingot. The material constituting such segregated sections is defective in strength, and when rails or structural material are rolled from ingots containing such defects, the strength of the resulting product is seriously impaired. Like piping, segregation is caused by the unequal rate at which the solidification of the ingot takes place. It will be remembered that the inner portions are last to solidify, and experience has shown that there is a tendency for the sulphur and phosphorus to be concentrated in these sections by liquidation.

In starting to investigate the conditions responsible for segregation, it was reasoned that the addition of some metallic material could be made to the steel while in its molten form which would throw light upon the subject. A number of experiments were conducted with various metals, and copper was finally selected for the purpose because its specific gravity is slightly greater than that of steel, and also because its color would make its presence apparent when the ingot was broken up. The results of experiments conducted along this line brought out several interesting points. A sand head was used on the ingot molds in order to maintain a liquid riser at the top, and additions of molten copper made at different lengths of time after pouring the steel penetrated those portions of the ingot where piping usually takes place, and thus indicated the exact location where inter-crystalline unsoundness or segregation is developed. It may be mentioned in this connection that such inter-crystalline unsoundness is not seen in the fracture of an ordinary ingot when cold; it is revealed upon a polished and etched section. By making additions of copper at different lengths of time after pouring the ingot, the rate at which the solidification of the steel takes place was determined, as the copper was unable to penetrate steel which had already reached the solid form. It may be mentioned in this connection that these experiments proved that the steel in the inner portions of the ingot remains in a liquid condition for a far longer period of time than was supposed. It can, therefore, be readily understood why there is a greater tendency towards segregation in large ingots. The obvious conclusion is that the greater length of time in which the metal remains in a molten condition offers a greater opportunity for the concentration of sulphur and phosphorus in the central section. This is in line with a long-known fact that the more rapidly solidification takes place, the greater is the reduction of the tendency towards segregation.

The author believes that these experiments should throw some light upon the nature of the phenomena which occur in the cooling down of molten steel to a solid condition, and it would appear that the method outlined presents a valuable source of information in regard to conditions affecting the rates of cooling, segregation and liquidation of steel.

* * *

A pin should not be put through a shaft that transmits a considerable amount of power. If collars or other parts have to be fastened to the shaft, it is better to hold them with one or two keys, as the weakening effect on the shaft of the keyways is not as great as that of a pin hole.

* * *

COMING EVENTS

November 11-16.—Second International Exposition of Inventions in St. Louis, Mo. F. W. Payne, secretary-manager, St. Louis Coliseum Co., St. Louis. Inventions covering a wide scope will be shown, applicable to every profession or trade.

December 3-6.—Annual meeting of the American Society of Mechanical Engineers in New York. Calvin W. Rice, secretary, 29 W. 39th St., New York.

SOCIETIES, SCHOOLS AND COLLEGES

National Machine Tool Builders' Association. Official report of the semi-annual convention at Atlantic City, N. J., May 16 and 17. James H. Herron, general manager, Cleveland, O.

American Association of Commerce and Trade, Berlin, Germany. Year-book giving officers, board of directors, roll of members, standing committees, annual reports, proceedings at annual meeting and statistics.

American Society of Engineer Draftsmen held its annual meeting in Teachers College, Columbia University, October 1. This meeting was the most important yet held by the organization. A chart was displayed by the president, Mr. E. Farrington Chandler, showing that the membership had quadrupled in the past year. A program comprising interesting constructive features was adopted for the coming year, which included the establishment of a mutual benefit section. The officers elected for 1913 are: Prof. Charles W. Weick, of Columbia University, president; William B. Harsel, first vice-president; and Charles A. Clark, of the Crocker-Wheeler Co., second vice-president. Walter M. Smyth, 116 Nassau St., New York, is the secretary.

NEW BOOKS AND PAMPHLETS

Digest of Workmen's Compensation Laws. 56 pages, 6 by 9 inches. Published by the National Association of Manufacturers, 30 Church St., N. Y. Library edition, 30 cents; paper cover, 15 cents.

A large number of bills concerning compensation of injured workmen have been presented to the state legislatures for enactment during the last two years. The purpose of this work is to form a reference work for the legislator, lawyer, insurance expert, employer and employe in the form of a synopsis of each law, so arranged that a comparison of the laws can be made easily. It is a work that should be available in every manufacturing plant.

The Freezing Point, Boiling Point and Conductivity Methods. By Harry C. Jones. 75 pages, 7¾ by 5½ inches. 15 illustrations. Published by the Chemical Publication Co., Easton, Pa. Price $1.

In preparing the second edition of this book, the author has gone over the text with the view of correcting a few minor errors which existed in the first edition, and has also made the necessary changes to bring the work up to date. The usual texts dealing with this subject have been prepared to meet practical requirements of the laboratory or the theoretical considerations which are dealt with in the class-room. The present book has been compiled with a view of combining the theoretical discussions and practical laboratory methods in the same volume, as it is believed that this is the only way in which an adequate knowledge of the subject can be secured.

Steam Boilers. By W. Inchley. 412 pages, 7½ by 5¼ inches. 140 illustrations. Published by Longmans Green & Co., New York City. Price $2.40.

An attempt has been made in the presentation of this text, to produce within the confines of a book of reasonable size, the principles governing the construction and operation of steam boilers and their accessories. The object in so doing has been to present information in a form suitable for the use of steam users and engineering students generally. Technical details of boiler construction, such as the pitch of rivets, strength of plates, etc., have been purposely omitted, as few readers will find themselves called upon for expert knowledge on such questions. Only the general principles of the strength of parts has been entered into, and higher mathematics has been eliminated wherever possible. It was obviously out of the question to include a complete discussion of all types of boilers and boiler accessories in a book of this size, but an effort has been made to include those types of equipment which have proved most satisfactory in practice.

The Theory of Machines. By Robert W. Angus. 238 pages, 9¼ by 6¼ inches. 147 illustrations. Published by the Engineering Society of the University of Toronto, Toronto, Canada. Price $2.25.

During the writer's experience as an engineer and instructor in engineering subjects, he has had frequent occasion to enter into a discussion of the general theory of the operation of various machine parts. In many cases, it is merely a question of designing such parts to give them sufficient strength, and the principles involved in work of this kind are naturally of the utmost importance in the engineering profession. In such work, however, no direct attempt is made to analyze the conditions under which the machine operates with a view of determining the requirements of size and strength. It was the author's appreciation of the need of such training for engineering students that led to his writing the present book. He does not claim complete originality in the material which he presents, as the current periodicals have been drawn upon wherever desirable information was available. But the quantity of such information was extremely meager and the majority of the text has been developed by the writer, for presentation in this volume.

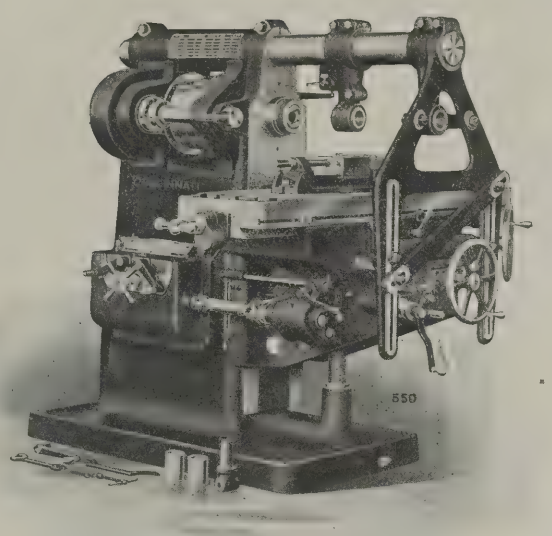
Elementary Machine Drawing and Design. By Wm. C. Marshall. 320 pages, 6⅜ by 9⅜ inches. 181 illustrations. Published by McGraw-Hill Book Co., New York. Price $3.

The material in this book has been arranged in such a way that the work can be undertaken by students of engineering who have already had a course in orthographic projection but who are not yet familiar with simple machine elements or with the subjects of mechanics or strength of materials. The simple forms of machine elements are taken up and current drafting-room methods of drawing them are presented, together with the standard practice in proportioning them for different operating conditions. In connection with this part of the work, test problems are presented at the end of each chapter to give the student practice in applying the principle of design which he has gone over. The book is not intended for home study but rather as a supplement to class-room talks on the subject matter presented. On this account detailed instructions have been omitted in many cases in order to allow the instructor the opportunity to vary the presentation of his subject according to individual requirements.

Modern Organization. By Charles De Lano Hine. 110 pages, 7½ by 5¼ inches. Published by the Engineering Magazine Co., New York. Price $2.

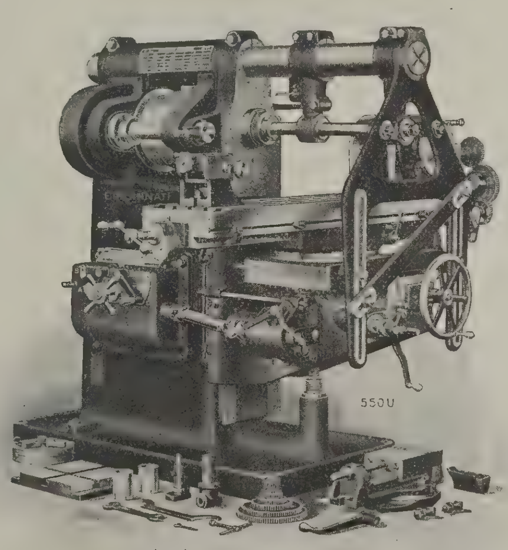
The text of this book was originally presented in a series of articles published in the *Engineering Magazine*, during the period from January to July, 1912, and represents the philosophy of management which Major Hine has had peculiar opportunities of demonstrating. This philosophy, as expressed in the unit system of organization directed toward promoting efficiency in operation in one of the great engineering industries, has been applied upon a scale of magnitude

Much of the Milling in most Shops is not Heavy Cutting



The No. 4 Plain High Power Miller with Cone Drive

Front or operator's side showing arrangement of all operating levers



The No. 4 Universal High Power Miller with Cone Drive

On this work the very powerful single pulley millers do not increase production.

An up-to-date, properly designed, cone-driven machine like our No. 4 Horizontal often proves the better investment.

It is our High Power Miller with cone-driven spindle.

We have simply replaced the Single Pulley, Geared Spindle Drive box with a Double Back Geared Cone of large diameter.

It has ample power for all that work requiring a large machine, but not excessively heavy cutting.

It can be depended upon for long, hard, continuous service, because of its massive "High Power" construction.

Its maintenance cost is low because of its simplicity.

AND IT IS HANDY.

The Feed Changers and Back Gear Lever are where the operator stands to shift the belt.

The Table always feeds in the direction in which the Engaging Lever is set.

This same lever also reverses the feed.

All Controlling Levers are at the front of the knee and saddle. So is the Quick Return.

Everything that has to do with its operation is within easy reach.

And there is an additional lever at the side of the knee controlling the feeds from behind the table, for end-milling or boring or similar work which can't be successfully done when the operator stands in front, as he must do on all other Millers.

Let us help on your milling problems. We make the largest variety of machines and therefore can recommend the ones best suited for your work.

THE CINCINNATI MILLING MACHINE CO.

CINCINNATI, OHIO, U. S. A.

ARGENTINE AGENTS—Robert Pusterla & Co., Buenos Aires.

which has only been approached in one other case. Its success was declared with conviction in specially informed circles, but outside of a chosen audience, the characteristics of Major Hine's work had not been effectively presented until the publication of the articles previously referred to. The ideas embodied are so fundamental in character, that it appears certain that they will exercise a powerful influence in many fields of industrial organization. The policies advocated are most interesting because they depend so little upon mechanism of any kind, so little upon systems affecting the rank and file of equipment, and so much upon the psychological influence, bearing first upon, and then through, the directing officials.

MECHANISM. By Robert McArdle Keown. 169 pages, 9⅜ by 6⅝ inches. 168 illustrations. Published by McGraw-Hill Book Co., New York. Price $2.

The material presented in this book is original in its method of presentation rather than in the actual information contained. The advisability of developing this text suggested itself to the writer owing to the desirable results which were obtained in class-room work based upon this arrangement. The distinctive features may be briefly outlined as follows: A discussion of motions, velocities and linkages are first taken up as they are comparatively simple for the student to understand, and problems can be given out in early stages of the class-room work. Cams are dealt with in detail, as they form part of a subject in which considerable practice is required. The involute system of gearing is taken up before the cycloidal system because it is generally easier for the student to grasp the subject when presented in this way. When the underlying principles of the involute system are thoroughly understood, it is generally an easy matter to master the cycloidal system. Furthermore, the use of the involute system is the more general in current practice. Problems are given at the end of each chapter in order that the student may familiarize himself with all of the principles which have been presented.

ELEMENTS OF DRAWING. By George F. Blessing and Lewis A. Darling. 193 pages, 6¼ by 9¼ inches. Published by John Wiley & Sons, New York. Price $1.50.

This book was prepared by the authors at the request of Dexter S. Kimball, professor of machine design and construction, Cornell University. The object in view was two-fold. First, to obtain a book exactly suited to the needs of an elementary course in mechanical drawing for those who were entering upon courses in engineering at Cornell University. Second, to put into permanent form a collection of ideas on the subject which had been accumulated as the result of past years experience. The authors have had experience both as technical educators and as practical engineers. This combination gives them an intimate knowledge of the requirements of the work in hand. Where the book is used as a text in teaching mechanical drawing, the object may be summed up by saying it is to instruct the student: First, how to select, care for, and use drawing instruments; second, how to make and read technical drawings; third, how to think over the drawing-board; fourth, to consider the relation a drawing bears to design, shop processes, and shop organization. In endeavoring to attain the last two objects, the parts of a wood-turning speed lathe have been adopted for models because it is believed that the average student's familiarity with these objects will enable him to combine with his drawing the necessary attention to design and manufacture of the part in question which is essential to the attainment of satisfactory results. The book also gives particularly good treatment to the subject of freehand lettering of drawings and to freehand sketching, both of which are points in which the average draftsman lacks proficiency.

NEW CATALOGUES AND CIRCULARS

ILLINOIS STOKER CO., Alton, Ill. Catalogue of chain grate stokers.

PNEUMATIC JACK CO., Paul Jones Bldg., Louisville, Ky. Circular of the Taylor pneumatic tandem jacks for car repair work and other railway uses.

NATIONAL SCALE CO., Chicopee Falls, Mass. Folder illustrating the National counting machine for counting screws, bolts, nuts, pins, small castings, printed matter, etc.

READY TOOL CO., Bridgeport, Conn. Circular illustrating the Hill compensating milling machine dog, designed especially for use when indexing taper work held on centers.

J. G. BLOUNT CO., Everett, Mass. Catalogue No. 14 on grinding and polishing machinery, and speed lathes, tailstocks, slide-rests, turrets, countershafts and other accessories.

TATE, JONES & CO., INC., Empire Bldg., Pittsburg, Pa. Circulars Nos. 140 and 141 on appliances for burning fuel oil, which apply to all purposes for which oil is used as fuel.

VULCAN ENGINEERING SALES CO., 2014 Fisher Bldg., Chicago, Ill. Circular of QMS jib cranes with hand and power hoists; QMS hand power traveling cranes; and QMS pneumatic hoists.

KEUFFEL & ESSER CO., 127 Fulton St., N. Y. Circular entitled "How to Select Drawing Instruments," illustrating the "Paragon" instruments, and describing their mechanical features.

CROCKER-WHEELER CO., Ampere, N. J. Bulletins Nos. 155 and 156 on Form Q induction motors for operating on 60-cycle polyphase alternating-current circuits, and motor-generator sets for all purposes.

W. S. ROCKWELL CO., 50 Church St., New York. Catalogue No. 15 on rotary annealing and hardening furnaces for annealing, hardening, tempering, blowing or other heat-treatment of brass, copper, steel and other metals.

WATSON-STILLMAN CO., 192 Fulton St., New York. Catalogue No. 84 on hydraulic accumulators and fittings, special hydraulic apparatus, reservoirs, etc. Seven principal types of accumulators are illustrated and described.

FIDELITY & CASUALTY CO., 92 Liberty St., New York. Pamphlet entitled "Steam-Boiler Explosions" by Wm. H. Boehm, an illustrated lecture delivered at Cornell University before the student branch of the A. S. M. E. May 3, 1912.

LUCAS MACHINE TOOL CO., E. 99th St. & L. S. & M. S. Ry., Cleveland, O. Circular describing new model No. 31 "Precision" horizontal boring, drilling and milling machine. The machine is furnished with a vertical milling attachment to order.

READING IRON CO., Reading, Pa. Pamphlet on characteristics of wrought iron pipe and steel pipe, showing the superior qualities of wrought iron pipe. The results of investigations are both interesting and valuable to users of steel and iron exposed to weather conditions.

TRIUMPH ELECTRIC CO., Cincinnati, Ohio. Bulletin No. 501 on "Triumph-Monitor" reversing motor planer drive, showing its application to a Cincinnati planer, the monitor controller, speed curves during reversal of the dynamic brake type, and the "Triumph-Monitor" equipment.

H. BICKFORD & CO., Lakeport, N. H. Leaflet illustrating and describing the 36-inch Bickford vertical chucking machine, designed and placed upon the market to supply the increasing demand for a low-priced, well made tool, suitable for chucking car wheels, gears, pulleys and work of this character.

LANDIS MACHINE CO., Waynesboro, Pa. Catalogue No. 20 on pipe and nipple threading machinery, illustrating the Landis tangent thread chaser, details of the Landis all-steel die-head, and other features of the machine. Six styles and sizes of the machines are illustrated, and specifications given.

PH. BONVILLAIN & E. RONCERAY, Paris, France. Catalogue No. 6 on foundry equipment and supplies, comprising cupolas, ladles, molding machines, furnaces, blowers, molders' tools, core-making machines, core ovens, blow-torches, pneumatic rammers, tumbling barrels, air compressors, templet cutting machines, pyrometers, etc.

VULCAN ENGINEERING SALES CO., 2014 Fisher Bldg., Chicago, Ill. Circular illustrating "Type 1M" cold metal sawing machine, the smallest metal sawing machine made by the company. This machine is especially adapted to meet the requirements of small shops. The machine has a capacity for rounds up to six inches diameter; squares, six inches diameter; and I-beams, ten inches vertical.

AMERICAN BLOWER CO., Detroit, Mich. Catalogue No. 343 entitled "Mechanical Draft Forced and Induced by 'Sirocco' and 'A B C' Blowers and Exhaust Fans." The catalogue calls attention to the natural advantages realized with artificial draft produced by mechanical means. It is illustrated with photographs of actual installations with a view to making clear the various methods of applying fans to steam boilers.

FAIRBANKS, MORSE & CO., Wabash Ave. and Eldredge Pl., Chicago, Ill. Pamphlet on the electrical equipment of the Louisville Planing Mill & Hard Wood Flooring Co.'s mill, showing the application of Fairbanks, Morse & Co.'s electric motors to double surfacers, inside molder, and Sturtevant blower. A schedule of all the motors in the installation giving horsepower and names of machines is included.

INGERSOLL-RAND CO., 11 Broadway, New York. Bulletin 4209 describing the Temple-Ingersoll electric air drill; Bulletin 4023 describing the 4-E type electric air rock drill; Bulletin 4025 describing the 5-F electric air rock drill; Catalogue 384-F giving instructions for installing and operating the Temple-Ingersoll electric air rock drills; and Form 601 giving instructions for operating 5-F machine and list of duplicate parts.

WESTINGHOUSE ELECTRIC & MFG. CO., East Pittsburg, Pa. Catalogue No. 10 on small motors for household and other purposes; descriptive leaflet No. 2444 on motor-generator flywheel sets; descriptive leaflet No. 2457 on commutating-pole rotary converters; descriptive leaflet No. 2359-A on direct-current commutating-pole motors—type SK; and descriptive leaflet No. 3506 on installations of paper mill motors for pulp mill service.

GENERAL ELECTRIC CO., Schenectady, N. Y. Bulletin No. 4958 on Direct-Current Railways of 1200, 1500 and 2400 volts. This bulletin comprises 129 pages descriptive of electric railway installations and equipment, profusely illustrated with halftones and line engravings; Bulletin No. 4978, Irrigation with Electrically-driven Pumps; Bulletin No. 4932, Electricity in the Brewing Industry; Bulletin No. 4976, Electric Drive in Grain Elevators and Flour Mills.

BROWN & SHARPE MFG. CO., Providence, R. I. Booklet entitled "Points About Grinding Wheels and Their Selection," taking up abrasives, bond, grade of wheels, selection of wheels, speed of wheels, combination of wheel and work speeds in cylindrical grinding, mounting wheels, balance of wheels, truing wheels, safety, use of water, suggestions for ordering grinding wheels, list of grinding wheels, suggestions on selection of wheels for use on B. & S. grinding machines, etc.

MESTA MACHINE CO., Pittsburg, Pa. Booklet entitled "Brief Description and Illustrations of the Plant and Product of the Mesta Machine Co., Pittsburg, Pa." This booklet is illustrated with halftones showing the buildings and interior views of the various departments of the company's plant, as well as a great number of illustrations of machines of various types built by the concern, including Corliss engines, air compressors, blowing engines, condensers, hydraulic forging presses.

TRAVELERS INSURANCE CO., Hartford, Conn., have begun the publication of a periodical called the *Travelers' Standard* which will deal with engineering matters of all kinds, but will be mainly concerned with safety engineering, as applied to construction work, manufacturing, mining, power generation and transmission, the electrical and chemical industries, and every other form of activity in which machinery or tools are used. The October number contains an article of general engineering interest entitled, "The Factor of Safety."

B. F. STURTEVANT CO., Hyde Park, Mass. Catalogue No. 205 on gasoline electric generating sets for isolated electric generating plants. These sets are built in 5 K. W., 10 K. W., and 15 K. W. capacities. They are admirably suited for electric lighting and power purposes on farms, country clubs, and other places remote from cities and sources of electric power supply. The catalogue illustrates details of construction, and will be found of general interest to all concerned with the problem of generating electric power with small units.

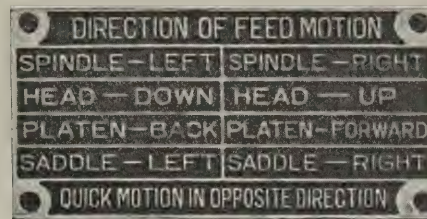
PENNSYLVANIA RAILROAD CO., Philadelphia, Pa., has issued a booklet for distribution in connection with the semi-centennial of the loyal war governors' conference of September 24, 1862, which was held in Altoona, Pa., September 24-26, 1912. The booklet is illustrated with views of the Conestoga wagon, canal packet on the old Pittsburg line, locomotive "Lancaster" and first steam train to the West; facsimile of original poster advertising schedule and rates to Pittsburg, and facsimile of original poster of schedule Philadelphia to Pittsburg trips in four and one-half days.

ARMSTRONG BROS. TOOL CO., 313 N. Francisco Ave., Chicago, Ill. Catalogue of tool-holders, comprising lathe, planer, shaper, slotter and other tool-holders; boring tools, drill-holders, cutting-off tools, side tools, lathe tool cabinets, knurling tools, grinding holders, cutting-off and grinding machines, high-speed steel, lathe dogs, boxed C clamps, planer jacks, drill drifts, blacksmiths' drill sockets, ratchet drills, drilling posts, drop-forged open-end wrenches, hexagon box wrenches, square box wrenches, construction wrenches, automobile wrench sets, socket wrenches, alligator wrenches, etc.

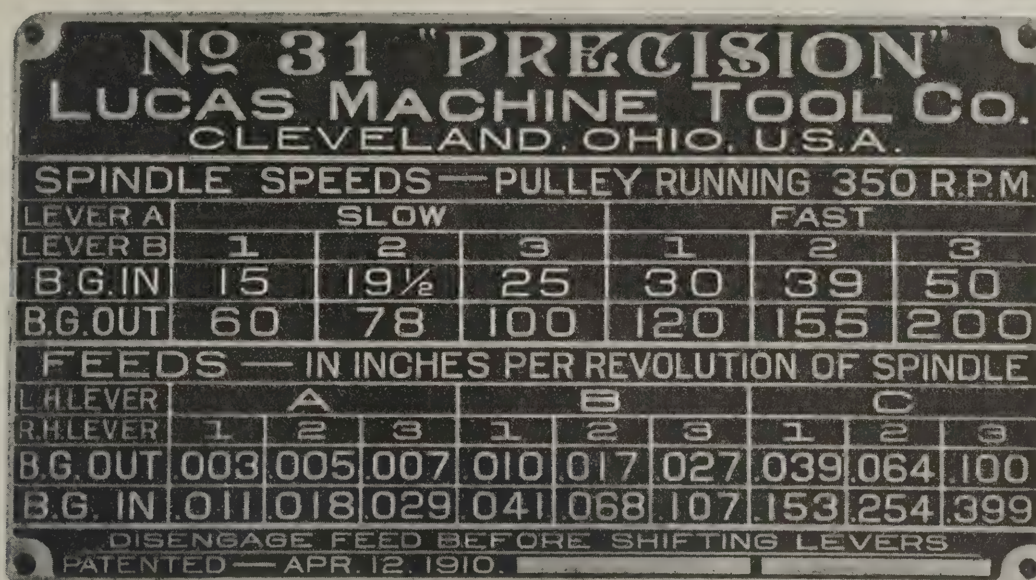
CROCKER-WHEELER CO., Ampere, N. J. Booklet on Ampere, showing its situation relative to New York and Newark, illustrating the plants, railway station, U. S. post office, interior of shops, and other features of mechanical interest, including one of the C. & C. motors made by the Curtis & Crocker Electric Co., the forerunner of the present Crocker-Wheeler Co. The history of the company includes brief biographies of Dr. Schuyler S. Wheeler and Prof. Francis B. Crocker. The booklet is an unusually interesting and attractive piece of literature on the physical and personal characteristics of a large manufacturing plant.

TRAVELERS INSURANCE CO., Hartford, Conn. Pamphlet on grinding wheels, being one of a series of text-books on safety of operation of plants and machinery. The pamphlet treats of emery wheels, stands, bearings, spindles, belt drive, flanges, washers, fitting of wheels, inspection of wheels, tightening nuts, tool-rests, speed, truth and balance, hoods, goggles, causes of accidents, grindstones, proper mounting and safe speed for same, and polishing wheels. Tables of speeds of emery wheels and grindstones, and illustrations of exhaust hoods,

ONLY TWO



PLATES



— ON THE —

"PRECISION" BORING, DRILLING AND MILLING MACHINE

One to show the speeds and feeds, and the other to show the direction of feeds, as the design of the machine is such that no other plates than these are necessary, the function of every lever being obvious and the feeds being of the same number and same value wherever used.

SIMPLICITY SECURES SUPERIOR SERVICE

LUCAS MACHINE TOOL CO., NOW AND ALWAYS OF CLEVELAND, O., U.S.A.

AGENTS—C. W. Burton, Griffiths & Co., London. Alfred H. Schutte, Cologne, Berlin, Brussels, Paris, Milan, St. Petersburg, Barcelona, Bilbao. Donauwerk Ernst Krause & Co., Vienna, Budapest, Prague. Overall, McCray, Ltd., Sydney, Australia. Andrews & George, Yokohama, Japan. Williams & Wilson, Montreal, Can.

CONTENTS FOR NOVEMBER

The first column of page numbers applies to the Engineering and Railway Editions: the second to the Shop Edition.

safety hoods, mounting for grinding wheels, etc., are included. The practical information and safety matters given in this little book, make it well worth the attention of every mechanical engineer, superintendent, foreman and mechanic.

Pratt & Whitney Co., Hartford, Conn. General office, 111 Broadway, New York. Catalogue of grinding machines, comprising four-inch by thirty-inch automatic cylindrical sizing grinder, six-inch by forty-eight-inch automatic sizing grinder, and three-foot and six-foot vertical surface grinders; circular illustrating and describing the Pratt & Whitney three-foot vertical surface grinder, and double and quadruple magnetic chucks for the rapid production of ground parts; circular of the Pratt & Whitney vertical shaper, designed to supply the needs of a machine suitable for doing regular slotting work which can also handle the work performed on the horizontal shaper; circulars of thread milling machines, spline milling machines and automatic profiling machines.

W. F. & John Barnes Co., 231 Ruby St., Rockford, Ill. Catalogue No. 71 of Barnes upright drills and other machine tools, comprising friction disk drills of 8- and 10-inch swing; upright drill No. 7, 15-inch swing with cone pulley drive, no back-gears, with or without gear tapping attachment; upright drills Nos. 1, 6, 1½, 2, 5 and 9 of 20, 22, 22½, 25 and 26 inches swing respectively; Nos. 2½ and 3 of 28 and 32 inches swing, respectively; upright drills Nos. 4 and 8 of 42 and 50 inches swing, respectively. Gear tapping attachments are furnished for all sizes of drills from 15 to 50 inches swing. The catalogue also illustrates and describes gang drills, horizontal radial drills, adjustable screw presses, motor drives for upright drills, water emery grinders, chucks, drill sockets, Barnes universal sliding chuck attachment, etc.

TRADE NOTES

National Machine Tool Co., Cincinnati, Ohio, will move into its new plant on Spring Grove Ave., about January 1, 1913.

Herbert L. Towle, advertising specialist, has removed to new offices in the Philadelphia National Bank Bldg., 421 Chestnut St., Philadelphia.

S. A. Woods Machine Co., Boston, Mass., the controlling interest in which was recently purchased by Messrs. C. W. H. Blood and H. C. Dodge, now has the following officers: H. C. Dodge, president, and C. W. H. Blood, vice-president and treasurer. The management in other respects will remain practically the same as before.

Ideal Case Hardening Compound Co., United States Rubber Bldg., New York. Pamphlet on casehardening, pack-hardening and annealing steel, containing in condensed form much useful information on the heat-treatment of steel and practical rules for securing the desired results. The pamphlet is one that should be welcomed by all concerned with the heat-treatment of steel. Sent free upon request.

Tate, Jones & Co., Inc., Empire Bldg., Pittsburg, Pa., is compiling a hand-book for the use of blacksmiths and forge-shop workers, which is expected to fill a long-felt want. The compilers request that blacksmiths and forge-workers send in handy receipts and shop kinks. Credit will be given for all these in the book. The effort is being made to compile the ideas of the leading blacksmiths throughout the country and thus make the book the best of its kind.

Brown Instrument Co., Philadelphia, Pa., and its associated company, the Keystone Electrical Instrument Co., have found a large increase in their shop facilities necessary and have arranged to triple the space after January 1. The two companies have had a very large increase in the demand for their pyrometers, thermometers and electrical instruments, and an increase in their factory equipment is necessary to meet the needs of the constantly growing business.

Walter H. Foster Co., 50 Church St., New York, has opened an office in the McCormick Bldg., Chicago, Ill., under the management of Mr. William Brewster, formerly associated with the Celfor Tool Co. The Walter H. Foster Co. will have the exclusive sale in that section for the Baush Machine Tool Co.'s multiple and radial drills, and the Lassiter bolt machinery; also the Quigley Furnace & Foundry Co. furnaces for all industrial requirements, complete furnace equipments, etc.

Sawyer Tool Mfg. Co., Fitchburg, Mass., maker of machinists' small tools, steel scales, etc., will move about November 1 to Ashburnham, Mass. eight miles from Fitchburg. The company has been in business in Fitchburg over ten years, and better facilities are now required to provide for the growth of the business. Three large brick buildings, affording 84,000 square feet of floor space or about seven times the area of the Fitchburg plant, will be occupied. Mr. Carl H. Hubbell is president of the company.

Hess-Bright Mfg. Co., Philadelphia, Pa., has built a new factory and office at Front St. and Erie Ave., having a frontage of 200 feet and a depth of 235 feet. The entire second floor, to the depth of 35 feet, is devoted to offices. Back of the offices the building is one-story high with sawtooth roof. The bulk of the company's product is imported, and the output of the shops will represent but a small proportion of the entire business. The present building forms the nucleus of a much larger plant which is eventually to be erected.

Greenfield Tap & Die Corporation, Greenfield, Mass., a holding company that controls the stock of the Wiley & Russell Mfg. Co. and Wells Brothers Co., acquired the entire stock of the A. J. Smart Mfg. Co. on October 1. The A. J. Smart Mfg. Co. was organized six years ago and quickly established a name for the manufacture of the highest class of taps, dies and screw plates. The company will be continued as a separate organization, and conditions are extremely favorable for the continuation of its rapid growth. The new officers are: President, F. O. Wells; vice-president, Rollin S. Bascom; treasurer and clerk, F. H. Payne; directors, the above, and M. Pratt and J. W. Stevens.

Taylor Iron & Steel Co., High Bridge, N. J., has acquired the business of Wm. Wharton, Jr., & Co., Inc. of Philadelphia, with works at Philadelphia and Jenkintown Pa., and its subsidiary corporation the Philadelphia Roll & Machine Co. The Taylor Co. and the Wharton Co. have both been in business more than fifty years. During the last eighteen years, the business of each company has been largely supplementary to the other in the application and manufacture of manganese steel, and the relations have become so close that a unity of interest has been found advisable. The new concern will be known as the Taylor-Wharton Iron & Steel Co., and the officers will be as follows: President, Knox Taylor; vice-presidents, A. E. Borie, Prof. H. M. Howe and V. Angerer; secretary and treasurer, W. A. Ingram.

Railway Edition for Locomotive Construction and Repair Shops

DECEMBER, 1912

TRANSCONA SHOPS OF THE NATIONAL TRANSCONTINENTAL RAILWAY

SOME CONSTRUCTION AND EQUIPMENT FEATURES OF A MODERN RAILWAY SHOP

BY GEORGE S. HODGINS*

W. J. Press, Mechanical Engineer of the N. T. Railway

THE National Transcontinental Railway is being constructed by the Government of Canada, with the intention of leasing it to the Grand Trunk Pacific Railway for fifty years. The Transcontinental, itself, extends from Moncton, N. B., to Winnipeg, Man., a distance of 1800 miles. At Moncton are the shops of the Intercolonial Railway, so that when the present undertaking is completed the Dominion Government will own a line from Sydney, on Cape Breton Island, to Winnipeg, Man.—a distance of about 2730 miles. The Intercolonial is both owned and operated by the government. The line from Moncton to Winnipeg will be operated by the Grand Trunk Pacific which is one of the subsidiary lines of the Grand Trunk Railway of Canada.

The following was, in part, embodied in an extensive and detailed report made to the Dominion Government by the writer, acting as consulting mechanical engineer of the National Transcontinental Railway. The writer was formerly connected with the mechanical department of the Canadian Pacific Railway, and has recently been engaged in technical journalism in New York. When the Government of Canada desired to secure an impartial expert opinion regarding shops and equipment, he was selected as a man who was no stranger to Canada and Canadian requirements, and yet had been out of the country long enough so that he would not be acquainted with those engaged on the work.

The Transcona shops were begun in 1909 with Mr. F. W. Walker in charge. On May 23, 1910, Mr. W. J. Press was

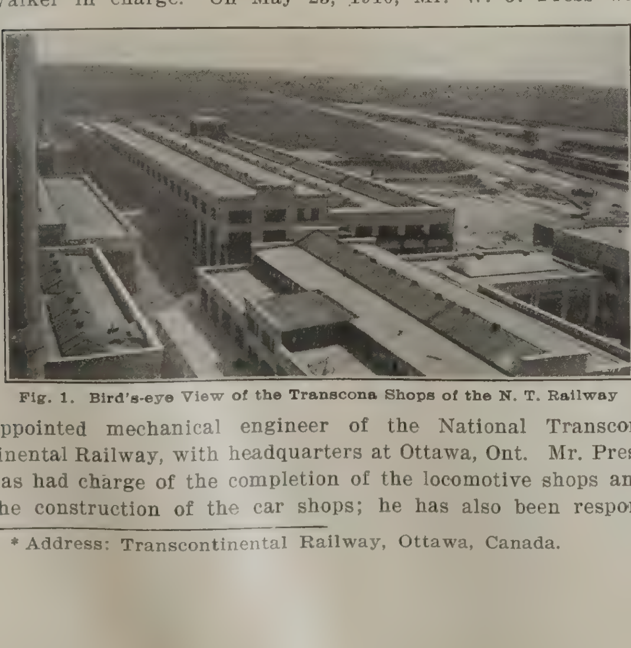

Fig. 1. Bird's-eye View of the Transcona Shops of the N. T. Railway

appointed mechanical engineer of the National Transcontinental Railway, with headquarters at Ottawa, Ont. Mr. Press has had charge of the completion of the locomotive shops and the construction of the car shops; he has also been responsible for the selection and installation of the equipment at Winnipeg, and all the other shops along the line. Mr. Press is an Australian, having served his apprenticeship on a government railway in his own country, where he worked in various capacities. He is, therefore, well qualified for service in building a road in Canada under governmental agency, where conditions are somewhat similar to those in Australia. Mr. Press served with the Royal Engineers during the Boer war, and was given charge of the principal locomotive and carriage shops of the Imperial Military Railways at Pretoria. During the war, he constructed a number of armored trains and had charge of the repair work on a railway taxed to the utmost by casualties among the operating force, and by the destruction and waste of war. It has often been the legitimate boast of mechanical men on a railway, that they are frequently compelled to do a great amount of work with very little material, but in this case ordinary failures were augmented by the wholesale destruction of serviceable locomotives. Over one hundred locomotives were blown up, others were disabled, and much ingenuity had to be exercised in order to keep things moving in the face of a lack of spare

Fig. 2. The Erecting and Machine Shop

parts and scarcity of material. In addition, the repairing of ordnance, gun-carriages, etc., was thrust upon the shop. After peace was declared, Mr. Press became works manager of the Central South African Railway Shops and later joined the staff of the Canadian Pacific Railway in Canada; later on he reentered government employ as mechanical engineer of the National Transcontinental Railway.

The Transcona Shops are built about five miles out of Winnipeg and are on ground slightly lower than the surrounding country. The soil is sticky clay and was overlayed with about four feet of gravel, so that although the surface is dry, the foundations are between ten and twelve feet deep. One of the most striking differences between these and other shops is the floor area and the number of pits. These shops are 612 by 170 feet in size, which gives a floor area of 104,000 square feet. A rough idea of the ratio of pits to floor may be gathered from the fact that there are twenty-four pits, the floor area per pit being about 4000 square feet. It must be remembered, however, that provision for growth has been made in the planning of these shops. The ratio of the floor area of the machine shop, to the area of the gallery is 1.45 to 1. These figures are only approximations, but in a general way they indicate the value of the floor space.

The grouping of the buildings brings the locomotive shops

* Address: Transcontinental Railway, Ottawa, Canada.

in close proximity to each other, and the car shops are also grouped together; the general shops that serve both locomotive and car shops occupy intermediate positions. The shop cranes have open lattice girders that do not seriously obstruct the light; they are operated by A. C. motors of special design, and each crane is equipped with an arrangement which automatically prevents the load being hauled up against the drum. When the lower pulley reaches a certain point, it throws out a limit switch on the lifting circuit and shuts off the current. The fall of a solenoid core results, and draws up a powerful hand brake; a mechanical brake also operates. The load can-

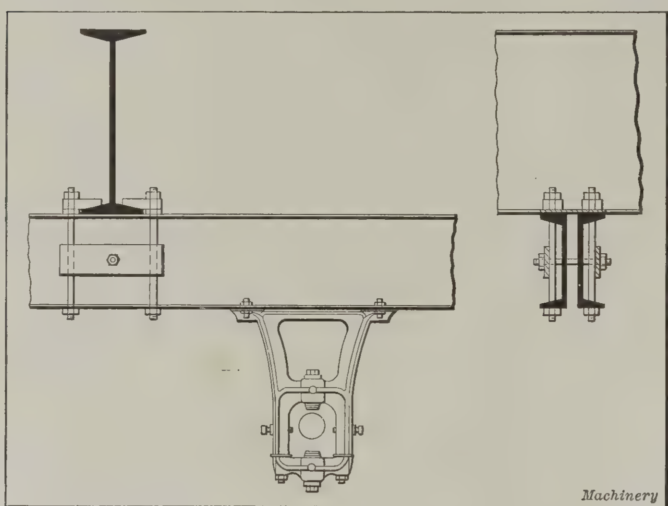

Fig. 3. Method of supporting Shaft Hangers in Transcona Shops

not be overwound, and the intentional release of the brake is necessary before the load can be lowered. The various switches and contacts are covered, so that the operator is protected from accidental contact with them.

The twenty-four working pits are placed at right angles to the length of the shop. This arrangement makes it necessary for an engine that is being placed over a pit or removed to be lifted by the 120-ton crane high enough to pass over the other locomotives. This method has the advantage of doing away with a transfer table, and of avoiding its first cost, maintenance and operating charges, which are necessarily high where the cold is severe and where the snow-fall, if not heavy, is sufficiently dry to drift readily. The cross pits also do away with a series of doors, with their liability to warp or be damaged and broken. Each locomotive enters and leaves by one of two doors, and is placed with the pilot facing the outer wall. The front end is opposite a window, and near a jib crane, one crane being provided for every two pits. These cranes lift smokebox doors, fronts, superheater pipes, etc., and thus leave the 10-ton shop crane to do the work for which it was legitimately intended, without being held up on "local" work. The pits are supplied with cold water and live steam. The pipes for compressed air and cold water, and the wires for electricity are on the posts nearby. The pipes in the pits are placed in grooves in the concrete walls so that they are not liable to damage by material falling on them.

In the machine shop, the tendency today is to replace general utility machines by more highly specialized ones. The old-time lathe and slotter have been largely replaced by machines designed to perform certain kinds of work at higher speeds and with greater facility. Modern multiple-head or turret drills replace the old-fashioned drill press, so that a number of similar operations can be quickly and accurately performed without the necessity of changing the tool.

A uniform method of setting all the machines has been adopted for the purpose of securing rigidity. The great majority of machines stand on reinforced concrete foundations about eleven feet deep. The machines are held by bolts bedded in the concrete, and the foundations are built up to within half-an-inch of the 3-inch plank floor. After being leveled and bolted down, concrete grouting is run around the machine base, flush with the floor and sloping slightly up to the base of the machine. This slight slope is provided to let the water due to condensation or moisture run off from the base of the machine, thus keeping it dry. The bedding of the machine in grouting makes it solid, with no tendency to work loose or to put any strain on the bolts. This method has also been applied to the shop posts, so that there is no tendency for an accumulation of water or moisture to rust or eat into the base of the columns.

The main lineshafting for one set of group-driven machines is in perfect alignment with that of the next set. In case of emergency, this arrangement would enable one group to be driven by the motor of the next group. For example, if motor No. 1 breaks down, one length of shafting can be taken down and have a coupling applied; the shaft may then be replaced and driven by motor No. 2. The hangers for the shop shafting—either main or countershaft—are bolted to steel channels placed on edge with webs inside. These channels are clamped to the steel I-beams of gallery or roof, the arrangement being shown in Fig. 3. Small cast-iron pieces with flat tops rest on the level surfaces of the I-beam flanges. The bolts, when tightened up, hold the small channels in place. Each set of clamping bolts is held together with a small plate and bolts which prevent slipping. These hanger-carriers are easily removed and are capable of application anywhere about the shop.

The placing of the machines has been carefully studied so that no reverse movement of material takes place. Rods, full-sized boiler plates, or other long material may be moved to and from the machines without dodging or swinging away to avoid obstructions, and large pieces can be worked on machines without fouling the posts or obstructing other opera-

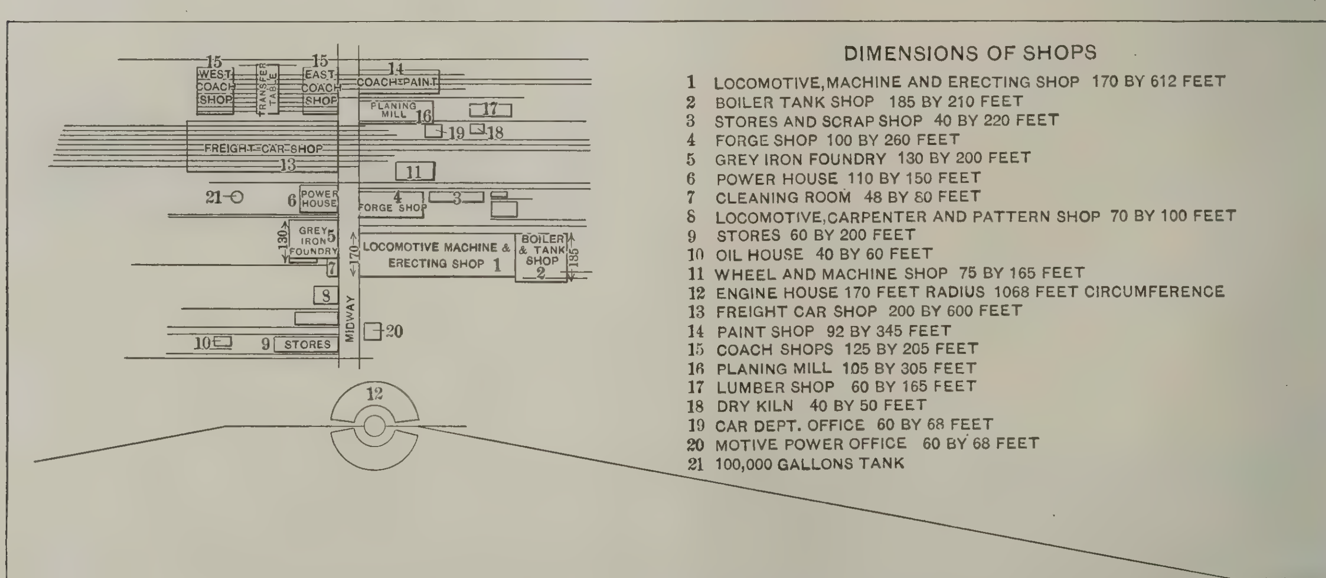

Fig. 4. Plan showing Layout of Shops of the N. T. Railway

tions. The straight-forward approach to each machine, and the adequate working area of each, has a beneficial effect on shop output.

In this shop, there are machines made in Canada, England and the United States. All have been selected on account of their merit, and the American machines give a good account of themselves. Near all large radial drills, pits have been provided so that any article of odd shape, that would not lie on the machine table, can be lowered into the pit and the drill arm swung over it. Belt-shifters and electric control handles of all machines have been placed with reference to the workman's convenience. This facilitates the operation of the machine and reduces the non-productive time and movement of the employe. A good example of a modern American machine used here is the Morton draw-cut cylinder planer and borer. This machine cuts on what would be the return stroke of an ordinary shaper, and gives a powerful stroke. The machine can plane all the flat surfaces of a locomotive cylinder casting, and bore the cylinders and piston valve chambers. It can mill out the steam and exhaust ports for a slide valve and drill all the holes in the cylinder and saddle. This machine is motor-driven, the motor being mounted on the machine. The wire connections which come up through the floor are contained in an upright iron pipe for protection. Flexible cable is used between stationary and moving parts, the cable being cased in a rubber hose.

Draw-cut shapers are used in the shop, on which the table is like a box and presents four surfaces. This box-like table can be revolved on a spindle. In case work has been set and is being done when a rush job has to be handled, the work in progress need not be taken off nor the setting altered. The table can be revolved so that another surface comes uppermost for the new work to be set on. After the new work is finished, the table can be turned back, and the original work proceeded with. This machine saves time and avoids discouraging the workman with two settings for one job.

The electric control for the riveting tower crane is placed on a level with the man who does the riveting. The crane-man does not ride overhead but stands beside the work. He is within speaking distance of those handling the boiler, and he can see what is going on without depending on signals. In the tank shop, an axle lathe is placed in a pit. The centers of this machine are approximately at the same height above the floor as the centers of an axle with wheels. The object of this is so that wheels can be rolled into this lathe without having to be lifted. The large boring machines have concrete pits below the floor so that the working parts, which are often inaccessible in other shops, can be got at with ease. A trap-door provides for entrance to each pit. The working parts are all below the surface and are open for inspection and adjustment. The Ryerson flue-rattler is below the surface, and the flues revolve in flowing water. Broken scale, etc., is effectively collected and removed. A circular pocket is located in the drain into which a bucket just fits. The flowing water fills the bucket and passes on, leaving the pulverized scale which sinks to the bottom; the shop crane draws the bucket and its contents out when required.

The locomotive shop is provided with two motor-driven air compressors, and the boiler shop with one. The pipes leading from the main air compressor in the power house are connected with these auxiliary compressors, the valves being so arranged that in case of breakdown, any of the other compressors can do the work. The shops may receive air from each other, or they may all draw air from the complete system. The locomotive compressors can supply the boiler shop, if both the main compressor and the boiler shop compressor give out. Likewise the boiler shop compressor can supply the locomotive shop, or the main compressor can supply any or all of the shops, in case the auxiliary compressors fail.

The large hydraulic flanger is provided with a simple safety feature. The opening, where the descending platen sinks below the floor, is protected at the edge by a wooden beading on the floor, so that a workman is not likely to get his foot caught between floor and platen. He cannot put his toes over the opening and keep his foot level, so that the unnatural position warns him of danger. The smithy contains steam hammers ranging from 200 to 5000 pounds. There is a pit at each side of these hammers provided with trap-doors. The pits give easy access to parts below, so that anvils may be leveled, and foundations inspected. This feature lessens cost and trouble, for in case adjustments have to be made, the shop floor is not encumbered and no time is lost making excavations. Among the machines in this shop is a cutting-off and centering machine. Axles forged here may be placed in this machine, cut to length and have a roughing cut run over them. They are then ready for shipment to outside stations, where they will be finished when used. Therefore, they do not have to be taken outside the smithy or handled in other shops. The whole of the Transcona plant at Winnipeg is an excellent example of modern design and equipment, of which the mechanical engineer and his staff may justly feel proud.

AUTOMATIC SPRINKLERS AND INSURANCE RATES

Figures gathered by the Chicago Association of Commerce, showing average insurance rates per $100 in that city, may be partially tabulated as follows:

	Buildings	Contents
Mill constructed buildings, with sprinklers....	$0.23	$0.32
Mill constructed buildings, without sprinklers.	.57	1.04
Ordinary constructed buildings, with sprinklers	.31	.40
Ordinary constructed buildings, without sprinklers	.77	1.19

If the contents of the average manufacturing or storage building are assumed to be worth double the value of the building, a general index for comparing buildings protected with automatic sprinklers and those not so protected is available. Mill constructed buildings on this basis will show an index of 87 for the protected building, whereas that of the unprotected building is 265, or more than three times as great a rate. This means that the reduction in the rate is 67.2 per cent. On the same basis, buildings of so-called ordinary construction would show an index of 111 when protected by automatic sprinklers and 315 when not so protected. In this case the reduction in the rate is 64.8 per cent. The saving effected by the installation of automatic sprinklers will ordinarily pay for the entire sprinkler equipment within a period of five years.

UNPROFITABLE REPAIRING OF TOOLS

Machines and tools are often repaired and kept in use when it would be more economical to buy new ones. Some men even pride themselves on what they call the savings resulting from this patching up of old tools. A story that illustrates the extremes to which this habit of repairing old tools rather than buying new ones can be carried was recently told by the mechanical engineer of a plant making machinists' tools.

A complaint was made to the sales department by a toolmaker, who stated that nippers of the firm's make did not stand up well. He mentioned in particular that when he worked at the Jones & Smith Co. one of these nippers was sent over to the toolroom for repairs at least twice a year. The tool in question did not cost more than $2, and had apparently been used for something like five or six years. When asked how long it took him to repair the nippers, the man making the complaint said: "Well, I should say about half a day." He was asked what wages he received, and promptly replied that he was a first-class toolmaker receiving forty-three cents an hour!

It requires no elaborate cost system to point out this moral; yet similar instances are not of unusual occurrence, particularly in the case of the smaller tools used around a machine shop, and the loss on such wasteful repairs may amount to a considerable sum during the year. Often this is caused by a mistaken theory of economy on the part of a foreman, but quite as often the general policy of the management of a shop is at fault. The foreman of the department or the superintendent of the plant has so often been cautioned by his manager against "unnecessary" expenditures, that he tries to avoid sending in requisitions for new tools and prefers to put one or more of his men to repairing old ones, because this work will not show up directly in the expense account, but will be charged to general repairs. Many a foreman remembers well how he has been requested to explain in detail the reason for buying a new device or tool costing but a few dollars, while at the same time wasteful methods of doing work which absorbed daily several times the cost of a new appliance, might be passed by unnoticed. What is needed is closer cooperation between the heads of concerns and the men in charge of the various departments. In many instances considerable economies could be effected if foremen and superintendents were encouraged to follow their own judgment with regard to the buying of new tools and the repairing of old ones; or if this policy in some cases would not be advisable, they should at least be encouraged to state their opinions freely, as it is likely that by their cooperation a great many false economies could be eliminated.

* * *

THE NEED OF POWER

The steam engine is such a common and necessary part of our civilization that few stop to think what a debt we owe to it. The need of man in his struggle with the crudeness and rawness of natural resources has been, is, and always will be for power. He is a comparatively weak creature, barely able to supply his physical needs by unremitting toil if unassisted. The first upward step from savagery was made when a cave man of splendid courage conquered the wild horse and trained him to carry burdens. The harnessing of horses and cattle to the plow was another great step forward that reduced manual labor and increased food production. Removed from the fear of immediate starvation, the needs of the mind as well as the body were ministered to and the march upward toward the civilized state was well begun.

But unhappily the opportunity to live on a higher plane was for only a few. The great mass was still submerged in poverty and in a state of actual or practical slavery. The ancient Greeks believed that civilization without slaves was impossible, and it was true of the conditions then existing. Without power other than that of animals, men must be employed to serve their masters to those comforts and luxuries that the higher life demands, but which the servers could not hope to enjoy themselves.

The invention of the steam engine and the great improvements made by Watt marked a new era which has had no parallel, and, therefore, is not comparable with any recorded epoch of the world's history. While elemental human nature does not change, the environment of man has so changed that predictions of the future based on the past are futile if not foolish. But we know that human servitude has not yet been abolished; it has taken on new forms less galling physically, but still intolerable to sensitive minds. How can liberty be attained? Only by acquiring the means of developing more power.

The growth of a great modern city is consonant with the development of power stations to supply its railways, lights, elevators, manufactories and other urban activities. The energy developed in one comparatively small unit is greater than all the available working force of some of the proudest ancient empires. The great Curtis turbine of the New York Edison Co., developing 30,000 H. P., is the physical equal of over a million men working in three equal shifts throughout the twenty-four-hour day. What a tremendous multiplication of the dynamic energy of the comparatively few men required to attend it and the boilers generating the steam needed to supply it! It is this great multiplier of human force, applicable in one way or another throughout the world, which is required to realize the ideals of the advanced engineer. To make the world small, to bring the produce of the uttermost parts to its markets and distribute the products of manufacturers to those who have furnished the food and crude materials is the great problem of the age. It is the problem of distribution that the engineer must solve as well as that of production; and power in all its many manifestations is the one great necessity for its accomplishment.

GAS ENGINE CAMS

It is a curious feature of gas engine design that the simple, primitive form of valve lifter cam, that is, the form in which the contour is made up of arcs and tangents, is less noisy than the more refined shapes which have often been proposed and but little used. To one familiar with the laws of mechanics and the general requirement to overcome the inertia of matter gradually and progressively to prevent shock, it is natural to conclude that an accelerated motion cam would work more smoothly and create less noise than that shape commonly used in which the lifter is practically a V-shaped boss on the side of a semicircular hub.

The article begun by Mr. Terry in the November number, and concluded in this number, exhaustively analyzes the conditions of gas engine cam action and shows why the primitive form is after all best. The article is lengthy, and so far as the conclusions are concerned it can be summed up in a comparatively few words, but we believe, nevertheless, that the space required for the elaboration of the analysis will be profitably used. It should settle once for all this question, which has caused no little discussion and perplexity among automobile engine designers. The case is one in which rule-of-thumb designing seems to have the best of it and theory to be at fault, but this is only apparent. When all the theoretical considerations are given their due weight, we can clearly see why the supposed refinement of cam design is not an improvement but actually a detriment.

REFORMING THE PUBLIC SCHOOL SYSTEM

As the defects of our public school system are brought out more and more by the educational deficiencies of the boys entering shops and factories at an early age, the more apparent it becomes that steps should be taken to correct them. Under the present system the public schools are open five days a week, from thirty-nine to forty weeks a year. The pupils go to school considerably less than two hundred days in the year; taking out the holidays, the average is about 190 days.

When it is considered that the children of the working classes have to leave school at fifteen or sixteen in order to contribute to the family support, the question is: "Why not try to improve the years when they can go to school"? Continuation schools are merely to make up for lost time. The average boy and girl in the towns and cities would be better off going to school six days a week fifty weeks in the year than loafing around, as many must, during the vacation period. This schedule would give them fifty per cent more hours of school work in a year, and that would be equivalent to two years extra schooling between the twelfth and sixteenth years. The boy who has to leave school at sixteen under this schedule should be as far advanced as he is at eighteen under the present system.

The arguments against the continuous school term are the strain on teachers, objections of parents, hot weather in July and August, and the need of pupils for long seasons of rest. As to the teachers, it is hardly necessary to point out that employes in stores, mills and factories work longer hours every day in the week and in many cases every week in the year. The parents' objections would become inconsequential when the benefits of the plan became apparent. School buildings can be made cool in summer, and will be made comfortable when the continuous school term becomes general. Pupils advance relatively faster when the school work is continuous. Several days or weeks are lost every opening term in the process of getting back into harness and regaining the receptive frame of mind largely lost during the vacations.

The continuous school term is being tried in several cities and towns with satisfaction. A feature of no little importance is that the better utilization of school buildings has lessened the need of new structures, meaning a saving of thousands of dollars annually in a large city. But the chief advantage is that the general adoption of the continuous school term will raise the educational standard of the workers' children to a plane that will better fit them for their duties not only as efficient industrial workers, but also as citizens.

LOCATING BALANCE WEIGHT CHAINS ON HORIZONTAL BORING MACHINES

BY W. G. DUNKLEY*

The most frequent problem met with in determining the correct location for the balance weight chains for the spindle slides of horizontal boring machines, is that in which the slide is under-balanced. In this case the difference in weight between the spindle slide and the balance weight is carried by the vertical screw. Consequently, there is a reaction on the slide, equal in value to the load on the screw, which acts along the axis of the screw. If the presence of this reaction is ignored, it will give rise to a turning moment on the slide which will cause the latter to bind on the upright. Such a binding action between the slide and upright would have been avoided if the proper means had been taken to locate the balance weight chains correctly. It will be readily understood from the preceding that the location of the balance weight chains is a matter of considerable importance in the design of horizontal boring mills.

In order to enter into this subject in detail, a case will be considered in which the spindle slide weighs eight tons and the balance weight only four tons. In this case, the reaction of the screw on the slide is equal to the difference between the weight of the slide and counterweight, or four tons. The load on each chain is two tons, as illustrated in Fig. 1, and, as a result, the vertical downward force of eight tons is balanced by the vertical upward forces, which have a total value of eight tons as shown. The slide is not in equilibrium, however, unless the moment of all the forces about any point is zero. If the moment of the vertical forces on the slide about any point is not zero, this moment must be balanced by a moment due to the reactions Q of the slide on the vees, because the slide is in equilibrium. In this problem, the friction between the slide and the face of the column is neglected. The center of gravity of the slide is located on the line CC which is ten inches from the screw. With this data at hand, the problem consists in determining the correct location for the chains. Bearing in mind that the reaction of the screw is four tons, the chains should be placed as indicated by the full line arrows, and with such an arrangement, the vertical forces are depended upon to keep the slide in equilibrium. There may still be a tendency for the slide to turn in a plane at right angles to the face of the upright.

Neglecting the reaction of the screw, the chains will naturally be placed at equal distances on either side of the center of gravity of the slide, as indicated by the dotted lines in Fig. 1. With such an arrangement, the turning moment of the vertical forces about an axis at the center of gravity will equal $4 \times 10 = 40$ ton-inches. This moment has to be neutralized by the moment of the forces Q which are determined as follows:

$$Q \times 60 = 4 \times 10 \times 2000 \text{ pound-inches.}$$

$$Q = \frac{4 \times 10 \times 2000}{60} = 1335 \text{ pounds}$$

This twisting action on the slide may attain a still greater value for increased inaccuracy in the location of the counterweight chains, but where these chains are properly placed, the presence of any twisting forces Q on the slide will be entirely avoided.

In some cases an additional chain is provided at the outer end of the slide, as shown at E in Fig. 2. Where such a design is adopted, it is necessary to provide an auxiliary standard to carry the balance weight. Where this practice is followed, it is necessary to be particularly accurate in designing; otherwise the arrangement is open to question, so far as the turning moment on the slide is concerned, but in any case the result secured will depend largely upon the location of the center of gravity of the slide. For example, if the slide shown in Fig. 1 were balanced according to the design shown in Fig. 2, the turning moment due to the vertical forces on the slide would be 130 ton-inches, 120 ton-inches of which would be due entirely to the force at E. In such a case, the amount

* Address: 25 Rothwell St., Manchester, England.

of the moment Q due to the reaction of the vees would be considerable, with the result that there would be excessive binding of the slide on the upright.

Let us next consider a case in which the center of gravity of the slide lies on the line DD shown in Fig. 2. The twisting moment due to the vertical forces would then be zero, and in such a case the action of the slide will be free from any tendency toward binding. There is one point about the arrangement shown in Fig. 2 that is particularly worthy of attention. Any alteration of the load at E will give a corresponding alteration of the reaction of the screw on the slide, which will result in a considerable variation in the twisting moment on the slide. This makes it possible to vary the load at E until the slide is properly balanced and binding action

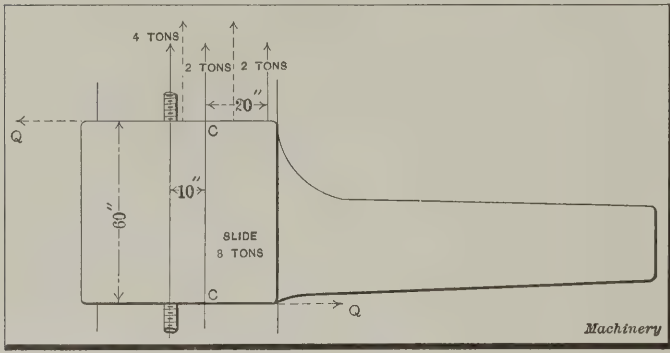

Fig. 1. Correct and Incorrect Methods of balancing Slide with Two Chains

eliminated; in this way, any inaccuracy in the calculation of the position of the center of gravity may be compensated for.

The calculation of the center of gravity of a heavy slide is not a simple matter, and as a result, it is apt to be avoided. This is obviously poor practice, as the proper action of the slide on the upright has been shown to be dependent upon having the counterweight chains correctly located in regard to the center of gravity of the slide. For example, the vertical hand adjustment of the slide is sometimes difficult to accomplish, and is made even more difficult if there is an excessive binding action between the slide and upright. In the preceding discussion, the balance of the slide has been treated for cases where the slide is stationary. Since there is binding action between the slide and upright, due to the resistance of the cut when working, it is obviously desirable that the binding action should be reduced to a minimum when the

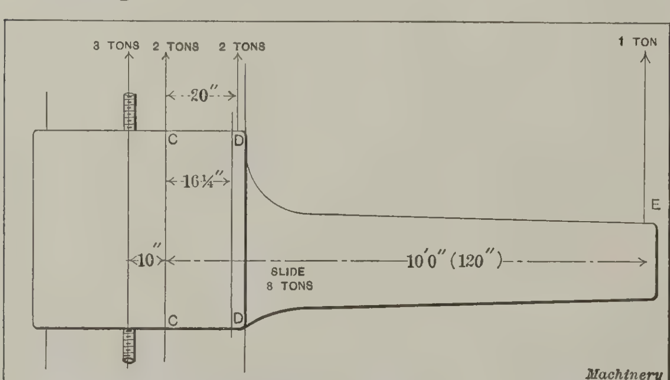

Fig. 2. Correct and Incorrect Methods of balancing Slide with Three Chains

slide is stationary. In some cases an attempt is made to put the screw under the center of gravity of the slide, but a consideration of the conditions shown in Fig. 1 will make it evident that there is no necessity for so doing in order to obtain a proper balance. For example, let us consider a case where the slide is engaged on a milling operation. In such a case, the force of the cut introduces an additional force between the screw and the slide, with the result that the turning moment on the slide, due to the force of the cut, is equal to this force multiplied by the distance between the screw and the line of the cut. It is thus evident that the screw should be as near the cutting face as possible, in order to reduce this turning moment to a minimum. If the screw is made to coincide with the position of the center of gravity of the slide, the distance to the face of the cut is increased; consequently it is not advisable to do this in order to obtain the desired balance of the slide, on account of the increased twisting moment that is introduced. The width of the guiding surface does not enter into the calculations in any way.

* * *

THE PYROMETER AND TIME STUDY IN STEEL TREATMENT

The general experience of a maker of lathe and planer cutters for tool-holders, outlined briefly in the following, shows how necessary are exact scientific methods to insure the production of uniformly satisfactory high-speed steel tools:

"Investigations in machine shops and tool-rooms indicate that the fault of most importance to the managers, is the lack of uniformity in results obtained from high-speed cutting tools. Many places were found where attempts were made to treat steel by faulty methods or with inadequate facilities. The lack of pyrometers, failure to use pyrometers when provided, hardening in charcoal furnaces insufficiently heated and treating without preheating, were a few of the practices noted that produced ununiform results—a few good pieces and many almost worthless.

"It seems to be the general opinion among those not getting results, that pyrometers are not of much use, that they do not give correct readings, and that better results can be gotten by depending on a man's experience than on any mechanical device. Now in the treatment of cutters we have had failures with pyrometers, but at the same time have found the cure for it, and that is frequent calibration. There is no question but what a man's eye is a better judge of the heat in a furnace than an incorrectly calibrated pyrometer.

"In the treatment of our cutters we have probably employed no more skilled men than are used in many large plants for treating high-speed steel, but the methods that they use and depend on are scientifically correct. Since the adoption of the improved Taylor-White treatment of high-speed steel we have sent out thousands of cutters and have received practically no complaints. Our experience has shown that a cutter treated today is the same as one treated six months ago and will be the same as one treated six months from now. We have tested all makes of high-speed steel, and have proved that with proper heat treatment any one of four or five of the real high-grade high-speed steels is entirely satisfactory and, in fact, cutters made from all of them cannot be told apart in use.

"All our cutters are preheated in a low-heated furnace at a temperature of 1350 degrees F. This heating takes out all strains in the metal and puts it in the best possible condition for bringing quickly to the high heat necessary to get the best results from high-speed steel. Every cutter from the smallest to the largest is treated in accordance with its sectional area and size. It goes from the low heat into the high heat furnace and stays there for a time that has been determined for each size by tests. We use pyrometers constantly on both furnaces, which are tested twice a week, having found that this is as long as they can safely go without being checked. The heat-treating room is provided with a specially made clock which starts on the pull of a lever by the man running the furnace, who knowing the proper length of time required for the cutter being treated, sets the clock accordingly. At the end of the predetermined time the clock rings a bell and stops, and the operator takes out a cutter and puts it into the proper medium.

"Our experience shows that it is necessary to bring the high-heat furnace to a temperature above the melting point of high-speed steel to get satisfactory results. This, of course, requires positive accuracy of the time chart as a fraction of a minute too much in the furnace would ruin the cutter, and too short a time would not give sufficient heat. Another reason for this is that to get the best results from high-speed steel, it is necessary to quickly raise the heat from 1350 F. to the highest heat required.

"We believe that the essentials for proper treatment of high-speed steel are: a first-class quality of high-speed steel, preheating, quickly raising the temperature of the steel to the proper quenching heat in a high-heat furnace, the use of accurately calibrated pyrometers and a correct time chart."

* * *

The Harvard engineering school has recently instituted all-the-year-round courses. The course for master's degree in engineering now can be taken in two years, there being no summer vacation. The students work from eight to ten hours per day, and the total vacations in the year amount to only about four weeks. The University of Chicago has also for some years maintained a summer term having equal weight with the other three-quarters of the year. This is a movement in the right direction. The inefficiency and waste of time due to the time-honored system of long summer vacations is out of place especially in engineering schools.

SPECIAL KNURLING OPERATIONS*

PRACTICE FOR THE BROWN & SHARPE AUTOMATIC SCREW MACHINES

BY DOUGLAS T. HAMILTON†

The knurling operations dealt with in the previous articles by the writer are what might be called "standard," and are met with frequently in automatic screw machine practice. The following examples are more of a special nature, and illustrate unusual applications of knurls. The data which follows should be of suggestive value to the designer of screw machine tools, inasmuch as it presents commendable methods of applying knurls to the work under varying conditions.

Bevel Knurling Tools Operated from the Turret

The simple bevel knurling tool shown in Fig. 2 is provided with a tapered shank and is held in a standard floating holder in the turret. The piece to be knurled, *A*, is a small German

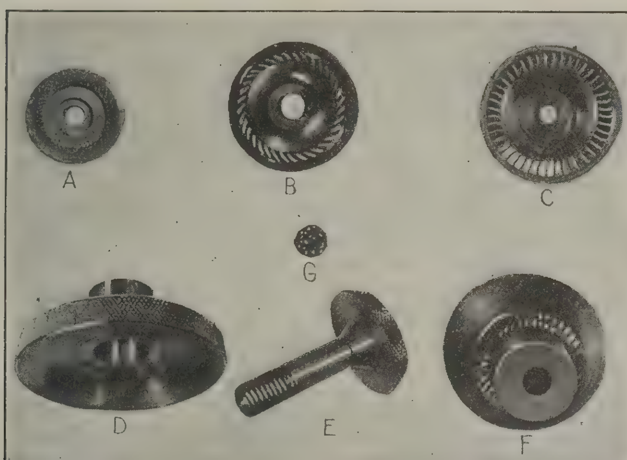

Fig. 1. Examples of Work requiring Special Knurls and Knurl-holder Applications

silver button which has a convex face, but as the curvature is slight, a straightface diamond knurl can be used. In applying the knurl to the work, the center line *BC* of the knurl should be at right angles to that portion of the work it is required to knurl. This particular holder was used in a No. 00 Brown & Sharpe automatic screw machine, which was operated at a spindle speed of 1492 R. P. M., and with a feed to the knurl of 0.0023 inch per revolution of the work.

Another example of end-knurling from the turret is shown

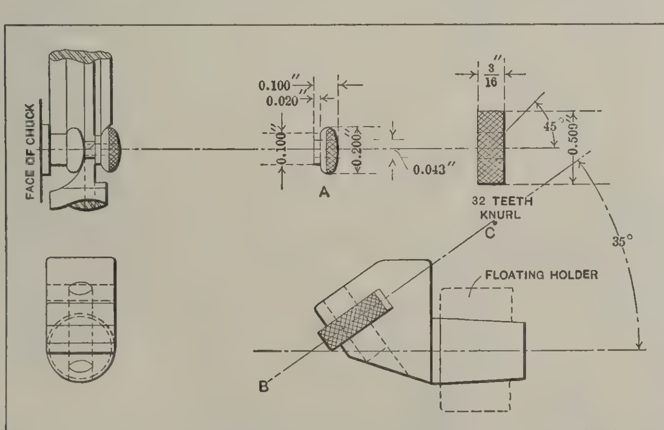

Fig. 2. End-knurling Tool held in Floating Holder

in Fig. 3. The piece to be knurled is shown at *A*, and also at *F* in Fig. 1. The knurl is presented from the turret under the body of the work, and produces a single spiral knurl, the teeth of which are at an angle of 25 degrees with the axis of the work. The holder is held in a No. 2 Brown & Sharpe automatic screw machine, and the work is rotated at 1200 R. P. M., with a feed to the knurl of 0.0024 inch per revolution.

The knurl holder consists of a shank *B* which fits the hole in the turret, and a holder *C* held to the body *B* by a screw, and located by a tongue and groove. The hole for screw *D* in holder *C* is larger than the body diameter of the screw, to provide for adjustment. The knurl which is shown detailed at *E* is provided with a shank which is a running fit in the

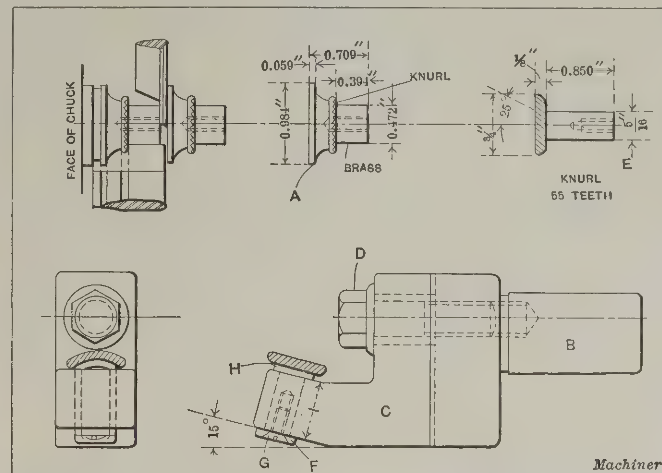

Fig. 3. End-knurling Tool held in Turret and operated at an Angle

hole in holder *C*. It is retained by a washer *F* and screw *G* and rotates on a hardened washer *H*. The distance *I* on the knurl shank is slightly greater than the width of the holder, so as to allow the knurl and washer *G* to rotate freely.

The knurl *B* and the knurl holder *D*, shown in Fig. 4, are

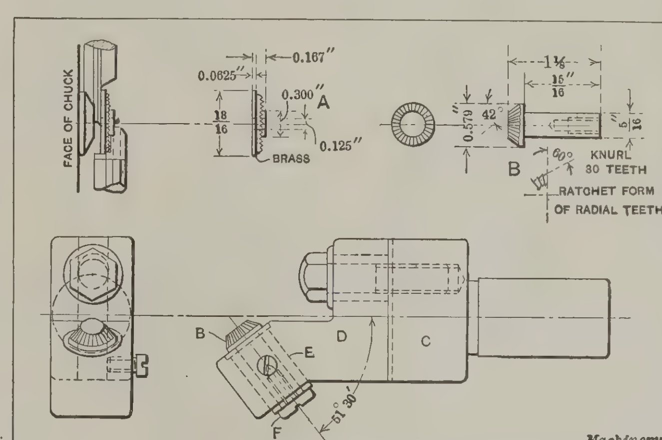

Fig. 4. Knurl and Knurling Tool-holder for producing Ratchet Form of Radial Teeth

used to produce a ratchet form of radial teeth in the shoulder of the piece shown at *A*, and also at *C* in Fig. 1. The teeth in the knurl are cut at an angle of 60 degrees and are radial with the center line. The work is rotated at 1216 R. P. M.,

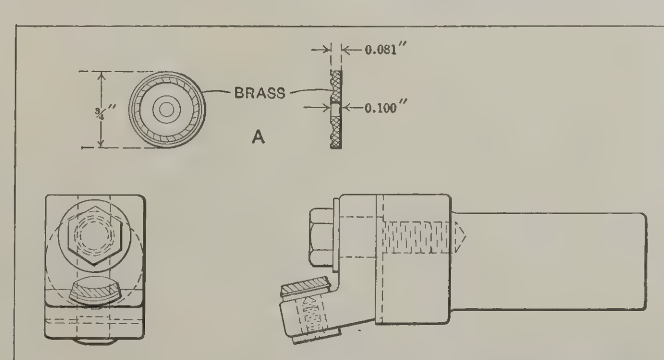

Fig. 5. Knurl and Holder for producing "Tangential" Form of Knurl

and a feed of 0.0008 inch is given to the knurl per revolution of the work.

This holder is held in the turret of a No. 2 Brown & Sharpe automatic screw machine, and consists of a body and shank *C* to which the holder *D* is held by a screw. The knurl *B* ro-

* See MACHINERY, June and July, 1909, "Knurls and Knurling Operations."

† Associate Editor of MACHINERY.

tates in a phosphor-bronze bushing *E* which is prevented from turning by a screw. The knurl is retained in the bushing by a large-headed screw *F* provided with a shoulder. There is sufficient end play to allow the knurl to rotate freely. It

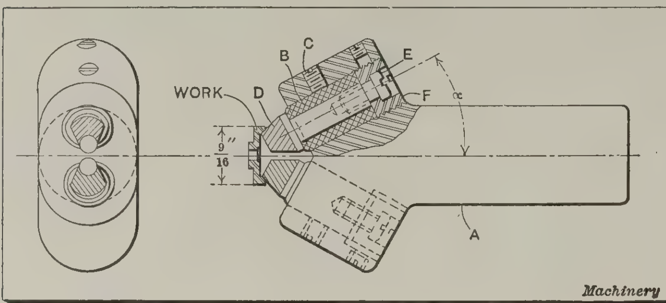

Fig. 6. Special Knurls and Holder for Internal Bevel Knurling

should be noted that in presenting the knurl to the work, the bottom of the teeth should be at right angles to the center line of the work holder.

A knurl holder having a marked similarity to that shown

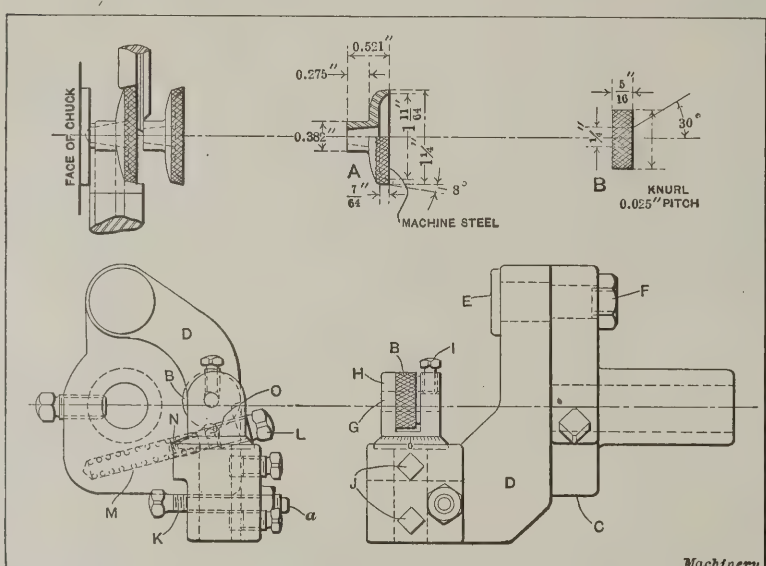

Fig. 7. Swing Type of Turret Knurl-holder for knurling at Various Angles

in Fig. 4 is illustrated in Fig. 5. In this case, however, the knurl is used for producing "tangential" teeth, as shown on the piece *B*, Fig. 1, and consequently it is provided with spiral teeth. It is not inclined at so small an angle with the center line of the holder, and approaches, when in operation on the work, as closely as conditions will permit, the action of a helical gear in mesh.

Internal Turret Knurl Holder

A special application of two bevel spiral knurls to the work is shown in Fig. 6. Here the portion of the work to be knurled is beveled at an included angle of approximately 90 degrees, and as shown at *A* in Fig. 1, a diamond-shaped knurl is to be produced. This operation can be more easily accomplished in this case with two spiral knurls than would be possible with one diamond knurl. Under these conditions it is advisable to have the angle *a* slightly less than half the angle on the work, so that it will be possible to use a bevel knurl, as a straight knurl would not work freely when operated from either the turret or cross-slide.

The holder *A*, Fig. 6, which is held in the turret, is made from a machine-steel forging and has two lugs, bored to receive the phosphor-bronze bushings *B*, these being retained in the holder by screws *C*. The knurls *D* are provided with shanks and are retained in bushings *B* by screws *E*, which rotate with the knurls. The end thrust of the knurls in this holder is considerable, so that it is necessary to back up the bushings *B* with screws *F*.

Special Swing Knurl Holder

A special knurl holder which is held in the turret and operated from the cross-slide by a rising block under the front tool-post, is shown in Fig. 7. The work is shown at *A*, and also at *D* in Fig. 1. It will be noticed that the work is considerably greater in diameter than that suited to the ordinary capacity of the No. 2 Brown & Sharpe automatic screw machine, thus requiring the use of a special outside feeding attachment, the ordinary feed tube being removed. The work is revolved at 240 R. P. M., and the knurl holder advanced at the rate of 0.00077 inch per revolution of the work. This is the speed at which the swinging arm *D* is moved, so that the actual feed of the knurl will be somewhat less than this amount.

The main body of holder *C* is provided with a shank held in the turret, and the swinging member *D* is held to its front face by a bolt *E* and nut *F*. The knurl *B* is held on pin *G* retained in the swivel holder *H* by screw *I*. The holder *H* is provided with angular graduations reading to degrees, so that the knurl can be set to the desired angle with the work. In the illustration the knurl is set straight, but in actual operation it is set around at an angle of 8 degrees. The shank of holder *H* is retained in the swinging member *D* by two set-screws *J*, which operate on bronze shoes to prevent marring the shank.

In operation, the rising block on the cross-slide comes in contact with the point *a* of the adjusting screw *K*, forcing the knurl into the work. The swinging member is returned to adjustable stop-screw *L* by a spring *M*, plunger *N* and pin *O*, the latter being driven into the swinging member and operating in an elongated hole in the holder *C*.

Special Opening Knurl Holder

An opening type of knurl holder is shown in Fig. 8. Two bevel knurls *B* are held in the swinging arms *C* and *D* in the manner shown in the sectional view. These arms are provided with offset lugs bored to receive the phosphor-bronze bushings *E*, which are prevented from turning by set-screws *F*. The knurls *B* are provided with shanks and are retained in the bronze bushings by screws *G*. The type of holder shown gives better results on the piece shown at *A*, and also at *E* in Fig. 1, than would a holder held on the cross-slide which would force the knurl straight into the work. The reason for this is that in operating a bevel knurl from the cross-slide on a tapered piece of work, the knurl has a tendency to glide off and produce an imperfect form of knurl. The opening type of holder obviates this difficulty to a considerable extent, as the power can be applied, so to speak, at right angles to the surface

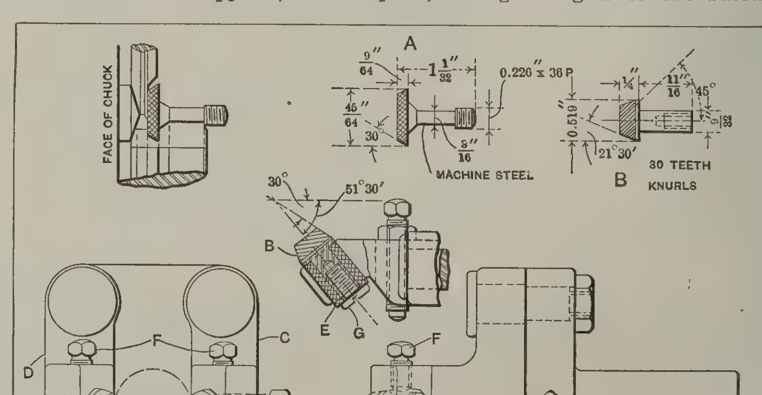

Fig. 8. Opening Type of Turret Knurl-holder for Bevel Knurling

knurled. The knurls are brought into position by the turret, and then fed into the work by the rising block on the cross-slide.

SPIRAL GEAR DESIGN*†—1

TO CALCULATE THE ELEMENTS OF FORTY-FIVE DEGREE COMBINATIONS

BY JAMES H. CARVER‡

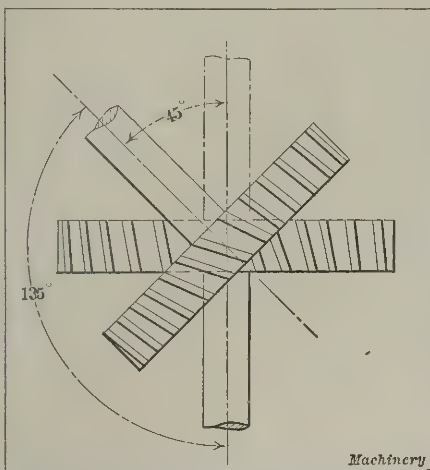

Fig. 1. Diagrammatical View showing General Arrangement of Spiral Gearing with Shafts at 45-degrees Angle

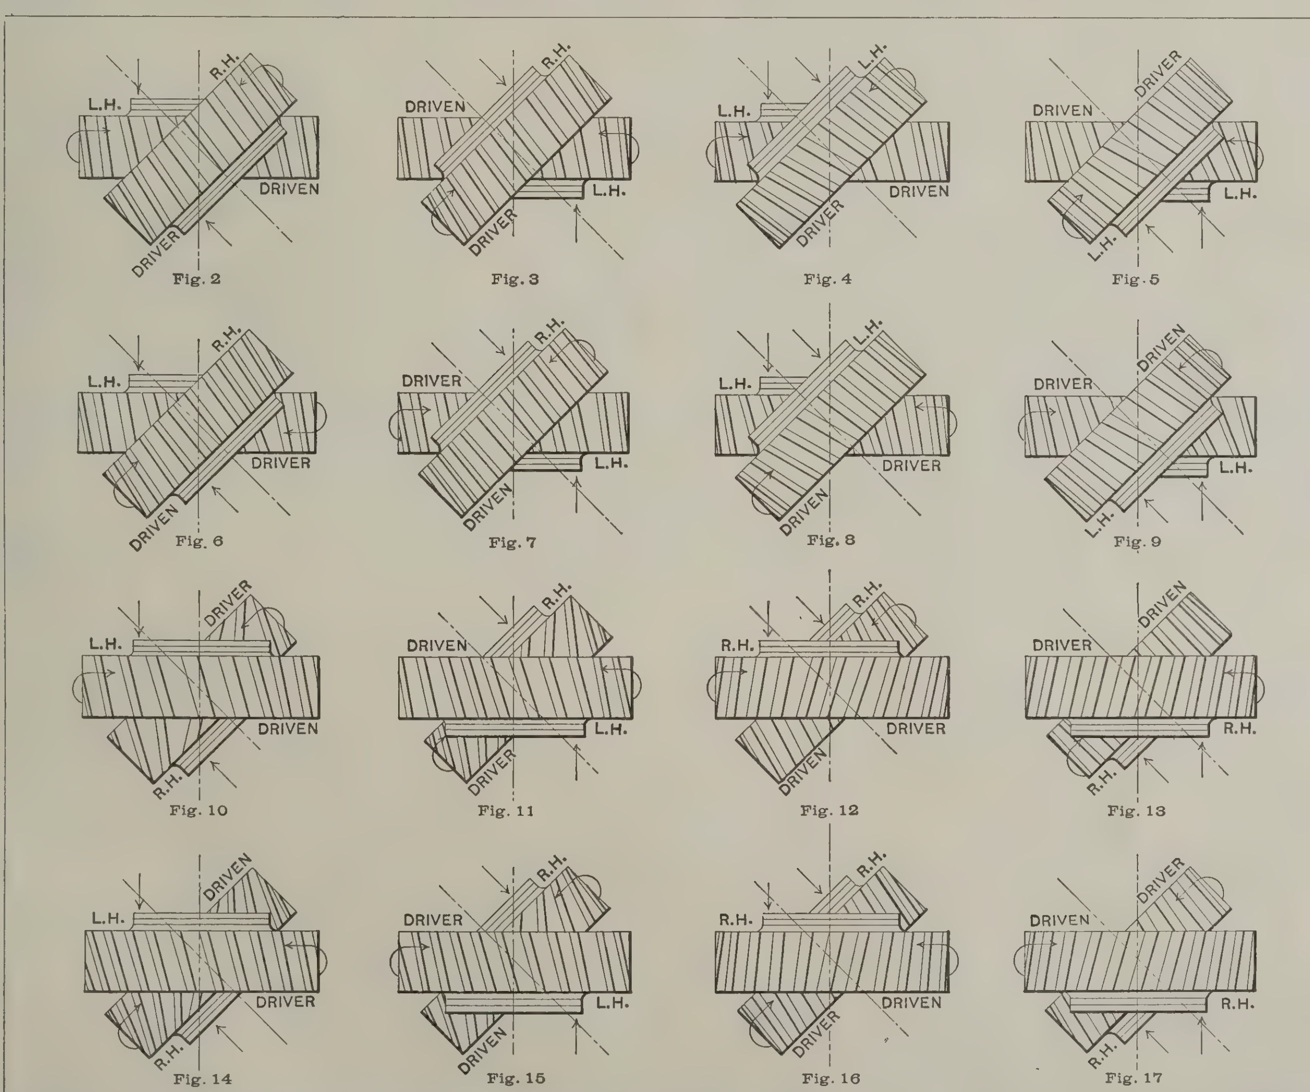
In the September, 1911, number of MACHINERY, the design of spiral gears with parallel shafts was dealt with, and in the October, 1911, number, spiral gears with shafts at right angles were treated. In the present article and in the accompanying Data Sheet Supplement, formulas will be given for calculating spiral gears with a shaft angle of 45 degrees. As seen in Fig. 1, the treatment, as far as the design is concerned, will be the same for a 135-degree shaft angle as for an angle of 45 degrees. Thrust diagrams Figs. 2 to 17 are given, the same as in the previous articles referred to, as an aid in determining the directions of thrust and rotation, and the direction of spiral, whether right- or left-hand. The arrows shown indicate the direction of the reaction against the thrust caused by the tooth pressure.

The relation between the direction of rotation, direction of spiral and spiral angle may be studied in Figs. 18 and 19. In Fig. 18 two spiral gears are shown, one in front of the other, with shafts at an angle of 45 degrees to each other. Line AB represents a right-hand spiral tooth on the front side of gear C. Assume gear C to rotate in the direction shown; then when the tooth AB reaches the rear side, it will be represented by line EF, which also represents the tooth direction on the front side of gear G. Angle BOH equals angle EOH, and it will be seen directly that the spiral angle of either gear equals 45 degrees minus the spiral angle of the other, both gears being right-hand. In Fig. 19 the spiral angles are shown to be of opposite hand, and one spiral angle is 45 degrees plus the other angle. From these illustrations we may draw the following conclusions relative to gears with a shaft angle of 45 degrees:

When the spiral angle of either gear is less than 45 degrees, then the spiral angles are the same hand, and one spiral angle is 45 degrees minus the other. When the spiral angle of either gear is greater than 45 degrees, then the spiral angles are of opposite hand, and the spiral angle of one gear is 45 degrees plus the spiral angle of the other.



Figs. 2 to 17. Thrust Diagrams for Spiral Gears with Shafts at 45-degrees Angle

The four cases which are dealt with in the accompanying Data Sheet Supplement are:

1. Shafts at 45-degrees angle, ratio equal and center distance approximate. 2. Shafts at 45-degrees angle, ratio equal

* With Data Sheet Supplement.

† See "Spiral Gear Design", MACHINERY, September, 1911, engineering edition, and the articles there referred to. See also MACHINERY'S Reference Book, No. 20, "Spiral Gearing", and MACHINERY'S Data Sheet Book, No. 6, "Bevel, Spiral and Worm Gearing".

‡ Address: 761 Eastern Ave., Schenectady, N. Y.

and center distance exact. 3. Shafts at 45-degrees angle, ratio unequal and center distance approximate. 4. Shafts at 45-degrees angle, ratio unequal and center distance exact.

The Data Sheet Supplement gives the required formulas for calculating gears for each of these cases. In the following the derivation of some of these formulas is explained.

1. Shafts at 45-degrees Angle, Ratio Equal, and Center Distance Approximate

As already stated, the spiral angle of one gear must equal 45 degrees plus or minus the spiral angle of the other. The formulas in the Supplement in Part (*a*) are to be used when the spiral angles of both gears are 22½ degrees, which will often be the case. The pitch diameter of both gears will be equal, and are found by the formula (see Data Sheet Supplement for notation):

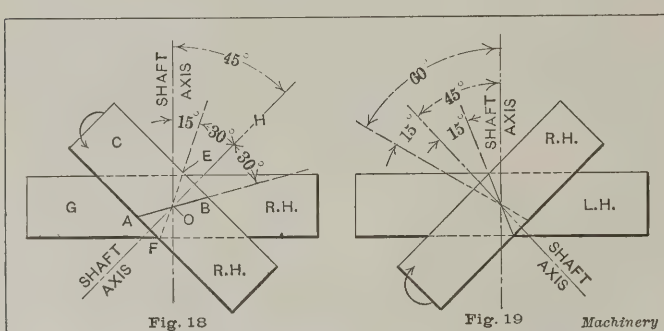
$$D = \frac{N}{P_n \cos 22\tfrac{1}{2}^\circ} = \frac{N}{0.92388\, P_n}$$

Further

$$T = \frac{N}{\cos^3 22\tfrac{1}{2}^\circ} = \frac{N}{0\ 788}$$

$$L = \pi\, D \cot 22\tfrac{1}{2}^\circ = 7.584\ D$$

The other formulas are the same as those given in the articles referred to at the beginning of this article. Part (*b*) is used for unequal spiral angles.



Figs. 18 and 19. Relation between the Spiral Angles of Teeth in Two Gears

2. Shafts at 45-degrees Angle, Ratio Equal, and Center Distance Exact

Following the same method of reasoning as in Case (6), "Spiral Gear Design", MACHINERY, October, 1911, the approximate number of teeth in each gear is found from the equation:

$$\frac{N}{P_n \cos \alpha_a} + \frac{N}{P_n \cos \beta_a} = 2\,C$$

from which, multiplying by $P_n \cos \alpha_a \cos \beta_a$,

$$N \cos \beta_a + N \cos \alpha_a = 2\ C\,P_n \cos \alpha_a \cos \beta_a, \text{ or}$$

$$N = \frac{2\ C\,P_n \cos \alpha_a \cos \beta_a}{\cos \beta_a + \cos \alpha_a}$$

After the exact number of teeth to be used in each gear is found from the last equation, the spiral angles are found from the same equation used in finding the approximate number of teeth.

Let $\dfrac{N}{P_n \cos \alpha} + \dfrac{N}{P_n \cos \beta} = 2\,C$, where α and β are now the exact spiral angles. The secant being the reciprocal of the cosine,

$$\frac{N}{P_n} \sec \alpha + \frac{N}{P_n} \sec \beta = 2\ C, \text{ or } \sec \alpha + \sec \beta = \frac{2\,C\,P_n}{N}$$

By using a table of secants, reading to minutes, angles can be found to satisfy this equation, after very few trials.

3. Shafts at 45-degrees Angle, Ratio Unequal and Center Distance Approximate

A formula for finding the number of teeth in the small gear is found from the equation:

$$\frac{N}{P_n \cos \alpha} + \frac{n}{P_n \cos \beta} = 2\ C$$

by solving for the value of n, the relation of N to n being:

$$R = \frac{N}{n}, \text{ or } N = Rn$$

Then multiplying by $P_n \cos \alpha \cos \beta$, we have:

$$N \cos \beta + n \cos \alpha = 2\ CP_n \cos \alpha \cos \beta$$

and substituting Rn for N:

$$n = \frac{2\ C\,P_n \cos \alpha \cos \beta}{R \cos \beta + \cos \alpha}$$

After finding the number of teeth N from the relation $Rn = N$, the pitch diameters are found in the manner previously described. In Part (*a*) are given the formulas to be used when both spiral angles are 22½ degrees. The constants were found from the numerical values of the functions in the formulas of Part (*b*), which latter formulas are used for unequal spiral angles in the two gears.

4. Shafts at 45-degrees Angle, Ratio Unequal, and Center Distance Exact

This case could be used under the same conditions spoken of in Case (8), "Spiral Gear Design", MACHINERY, October, 1911. The number of teeth is found exactly as in Case (3) of the present article, after which the exact spiral angles are found by trial from the equation:

$$R \sec \alpha + \sec \beta = \frac{2\,C\,P_n}{n}$$

which is found from the equations

$$\frac{N}{P_n \cos \alpha} + \frac{n}{P_n \cos \beta} = 2\,C, \text{ and } N = Rn$$

in the same manner as before. When using these equations for finding spiral angles, the table used must give values to minutes in order to insure accuracy.

HOW TO PATCH A CONCRETE FLOOR

When a cement floor surface becomes worn, it is often necessary to patch it. Mr. Leonard C. Wason, president of the Aberthaw Construction Co., Boston, in a recent paper describes the common, or wrong way, and the right way, as follows:

Commonly a sand and cement mortar is made, some cutting is done and the mortar is put in and scrubbed with a steel trowel until smooth. It is then covered up for a while. If the concrete under the patch is left dry, it soaks up the water of the mortar. As a result, the mortar does not set. If the room is dry or hot the surface of the patch dries out and for the same reason it does not set. If the concrete under the patch is dusty the patch does not adhere to the concrete. If the materials in the mortar are not suitable, naturally the patch wears badly, particularly as it is obviously located at a point of severe wear.

To proceed in the right way, cut down the worn place at least one-and-a-half inch. This cutting should be carried into the strong unbroken concrete and the edges should be cleanly undercut. The bottom of the cut should then be swept out, clean-blown out with compressed air or a pair of bellows, if available, then thoroughly wet and scrubbed with a broom. In this way, small loose particles of broken material which the chisel has driven into the surface are removed. A grout made of pure cement and water, about the consistency of thin cream, should be scrubbed into the pores with a broom or brush, both at the bottom and sides of the cut. Following this a stiffer grout, about the consistency of soft putty, should be thoroughly compressed and worked into the surface, which has already been spread with grout. Finally, before the grout is set a mortar made of one part cement to one part crushed stone or gravel, consisting of graded sizes from one-half inch down to the smallest, excluding dust, should be thoroughly mixed and put in place, then floated to a proper surface. Cover with wet bagging, wet sand, sawdust or other available material. All trucking should be kept off and the surface kept thoroughly wet for at least one week or ten days.

If a particularly hard surface is required, six-penny nails are sometimes mixed with the mortar and other nails stuck into the surface when the patch is finished. This will produce a surface which is extremely hard and durable.

* * *

When a man thinks that he is too old to learn, it simply means that he is getting either too self-satisfied or too stubborn and contrary, for there is no age limit to learning.

MAKING ANNULAR BEARINGS*

SOME OF THE MACHINERY AND METHODS EMPLOYED IN THE MANUFACTURE

BY ROBERT H. GRANT†

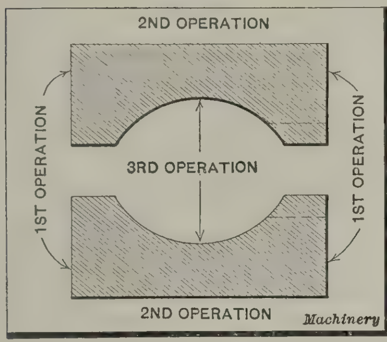

Fig. 1. Order of Grinding Operations on Races

The rapid increase in the use of annular ball bearings has led to many improvements in their design. Such improvements have required a corresponding development in the methods used in the manufacture of these bearings, until they have now reached a very complete stage. The inner and outer races were formerly made from separate pieces of bar stock and this method was responsible for a waste of at least eighty per cent of the raw material. This operation was improved by the writer so that both races were produced from the same bar, as described in a previous article in MACHINERY.

Use of Drawn Tubing

The next development in the production of the races came in the form of the tubing made by the Becker Steel Co., New York City. The smaller sized races can now be made very rapidly from this stock, using an automatic screw machine. The larger sizes are produced on Fay automatic lathes of the type made by the Jones & Lamson Machine Co., Springfield, Vt. In making the larger sized races, tubing or forgings of suitable size and material are used. The Fay automatic lathe shown in Fig. 2 has a worm-driven head which gives ample power for driving several tools at a time. The turning and facing tools are worked together, and the rounding of the corners is done by the same facing tools. The bar used for boring the races has two sets of tools inserted in it, the finishing tool starting right after the roughing tool has gone through the ring. Owing to the semi-automatic action of the machine, it is possible for one man to run four machines, thereby reducing the cost of machining to a minimum.

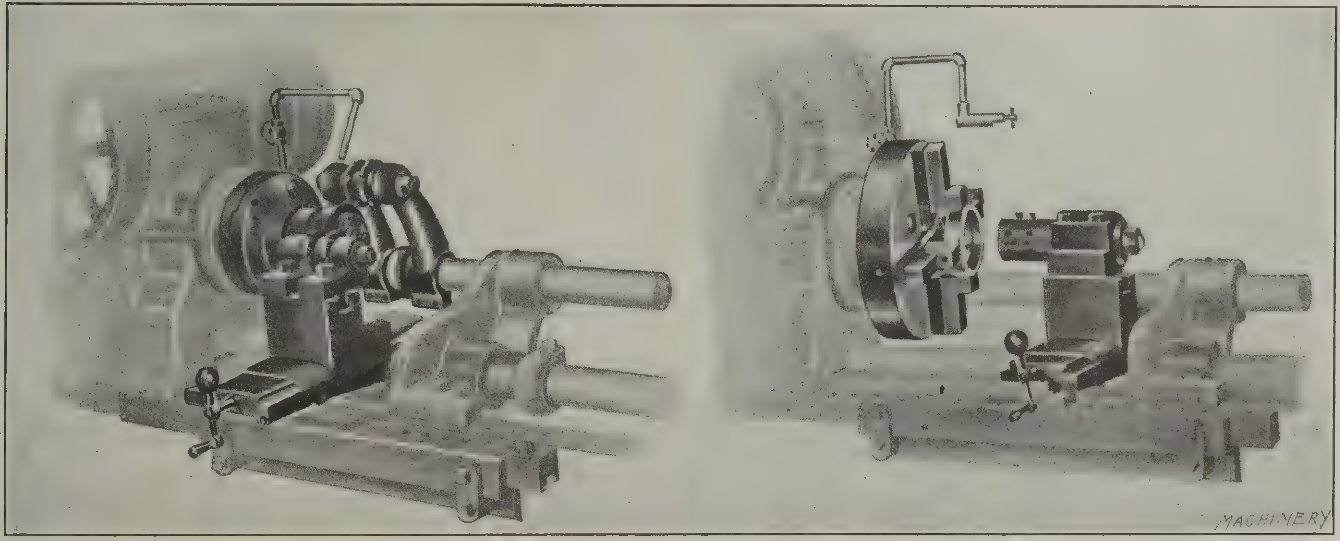

Fig. 2. Fay Automatic Lathe used for forming Blanks for Races

Hardening and Grinding

The extreme thinness of the bearing races makes it difficult for them to hold their shape. Consequently they must be very carefully treated in the hardening department. The method of procedure followed in the hardening operation was fully dealt with in a previous article in MACHINERY. After being hardened, the work is ready for grinding, the order of the operations being shown diagrammatically in Fig. 1. The first grinding operation, which consists of roughing out the blanks, has the effect of relieving the strains in the work. This important operation is performed on a Pratt & Whitney or a Blanchard face grinder. The work is held in a magnetic chuck so that a number of races can be ground at a time and still maintain the required degree of accuracy. The outer races are next mounted on a gang-arbor, as shown in Fig. 3; this arbor is considerably smaller than the hole in the work, the size being indicated in the illustration. A simple method of loading the arbor consists of having a V-block to support the work, and adjustable V-blocks that support the arbor at each end. These blocks are set in such a position that the work is centrally located on the arbor when the clamping nut is tightened. The work is now ready to be ground on the outside. The outside of the inner races is ground in the same way. The hole in the inner races is also ground in a gang fixture, as shown in Fig. 4. This will be seen to consist of a sleeve of the proper size to hold the work, which is secured between the shoulder at one end and a threaded cap at the other. When the sleeve has been loaded with work, it is held in a universal chuck. This method of grinding has effected a considerable reduction in the cost of manufacturing. The grooves in both the inner and outer races are rough-ground with a form wheel. After grinding, the work is allowed to

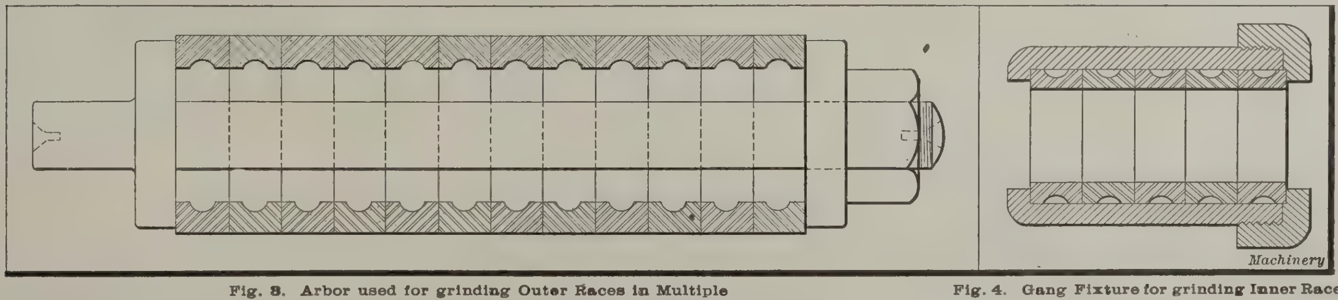

Fig. 3. Arbor used for grinding Outer Races in Multiple

Fig. 4. Gang Fixture for grinding Inner Races

* For additional information on the manufacture of ball bearings, see article entitled "The Manufacture of Steel Balls" published in MACHINERY for February, March and April, 1912; also article entitled "Ball and Roller Thrust Bearings" published in August, 1912, and other articles there referred to.

† Address: 912 Oakland Ave., Ann Arbor, Mich.

"rest" for two or three weeks, after which time it is ready for finishing. The high finish which is produced on the ball bearings of foreign manufacture has made it necessary for the American product to be brought to corresponding perfection in order to compete in the open market.

The grinding of the grooves in the races is, of course, one of the most important steps in manufacturing ball bearings.

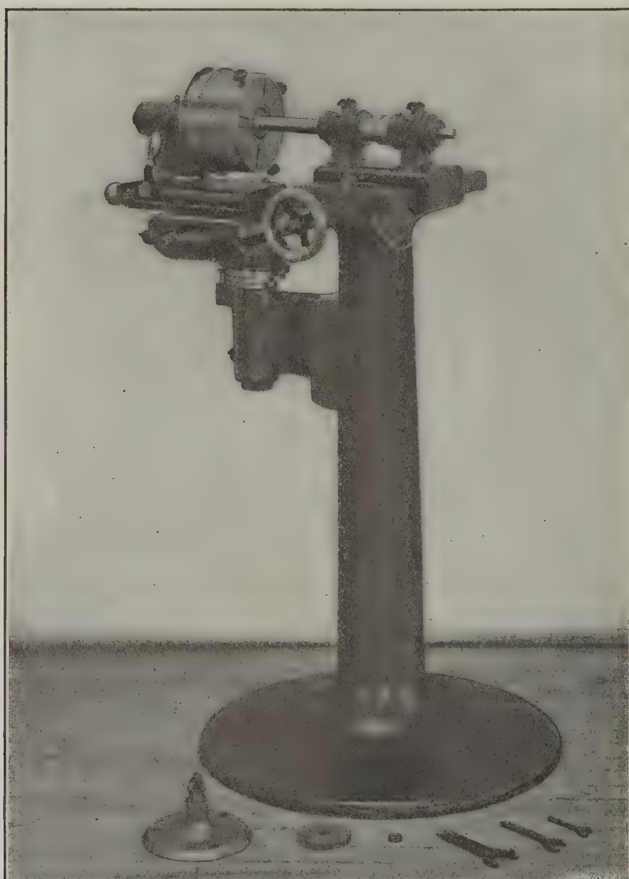

Fig. 5. Simple Form of Machine for grinding Grooves in Races

The machinery for doing this grinding has seen a great many improvements, and has now been brought to a stage where it is well nigh perfect. Fig. 5 shows the original type of grinder made for the trade by the Brown & Sharpe Mfg. Co., Providence, R. I. This was a very simple head that was mounted on one of the bases of the B. & S. No. 2 cutter grinder; the machine had a special head so that it could be used for radius grinding on both the inner and outer races. The column of the machine has a bracket attached to it, which is provided with a vertical adjustment and bored out to receive the grinder head that is equipped with two slides, thus providing for adjustment in two directions. The lower slide has a scale graduated on it, and a pointer is screwed to the bracket; this provides for setting the head over so that any radius can be ground, as the center of the wheel and the center of the bracket are kept in a direct line. The upper slide carries the work spindle and has a rack and pinion arrangement which provides for moving the head back from the wheel, so that the work can be measured at any time without disturbing the adjustment. This slide is also provided with an adjusting screw; in case the work which is carried in the spindle gets out of line with the wheel, it can be adjusted very easily. The work head has a pulley attached to it and is driven from the countershaft at constant speed. The slide which carries the wheel head is fastened to the base, and is equipped with stop pins that control the length of movement. The spindle runs in phosphor-bronze bearings, which are arranged with the usual form of take-ups so that they always fit closely. The drive is provided by two-step cones, to which a belt runs direct from the countershaft.

At the time of receiving our order, the Brown & Sharpe Mfg. Co. was so busy that it was unable to make us more than five of these machines, but the company lent us the patterns and sold us all the standard parts so that we were able to build these grinders in our own factory. The oscillatory motion of the head on this type of grinder was produced by hand and made it necessary to assign one man to operate each machine. This suggested the possibility of improvement by providing means for securing the oscillatory movement by power. The method by which this was finally accomplished, is shown in Figs. 6 and 7, where it will be seen that a bracket is attached to the column of the machine about 18 inches from the floor. This bracket carries a worm and worm-wheel, which are driven by a three-step cone pulley. A plate is mounted at the top of the worm-wheel spindle; this plate has a T-slot cut through its face so that the driving rod, which connects with the grinder head and produces the oscillatory motion, can be set at different distances off center. This provides for giving the work head any amount of throw which is necessary to grind the grooves in the races. The transmission of power from the plate on the worm-shaft to the grinder head is effected by a rack which is cut in the end of the connecting-rod. The teeth of this rack drive a suitable spur gear which is a loose fit on a shaft that is part of the lower work head slide. A plate is keyed to the shaft above this gear and carries a plunger that can be raised or lowered by a lever. When it is required to throw in the drive, this lever brings the plunger down into a hole in the spur gear and starts the head oscillating. Fig. 7 shows a machine of this type, and by referring to this illustration, together with the line drawing, the method by which the head is oscillated will be readily understood.

Holding the Races for Grinding

The next important advance which was made in the design of machinery for grinding the races of annular bearings consisted of an improvement in the method of holding the work. Formerly, the work was held in the head by means of a split ring and adjusting screws. These screws were manipulated to locate the work in the desired position; this was a very tiresome job, as it frequently took from five to eight minutes to get the races in a central position. Fig. 8 shows the improved method, which consists of taking the same head and inserting a hardened steel ring that is tapered on the inside. A master chuck was made to fit this taper and pads were then made to fit any race, the construction being similar to that used in an ordinary screw machine. A hole was drilled

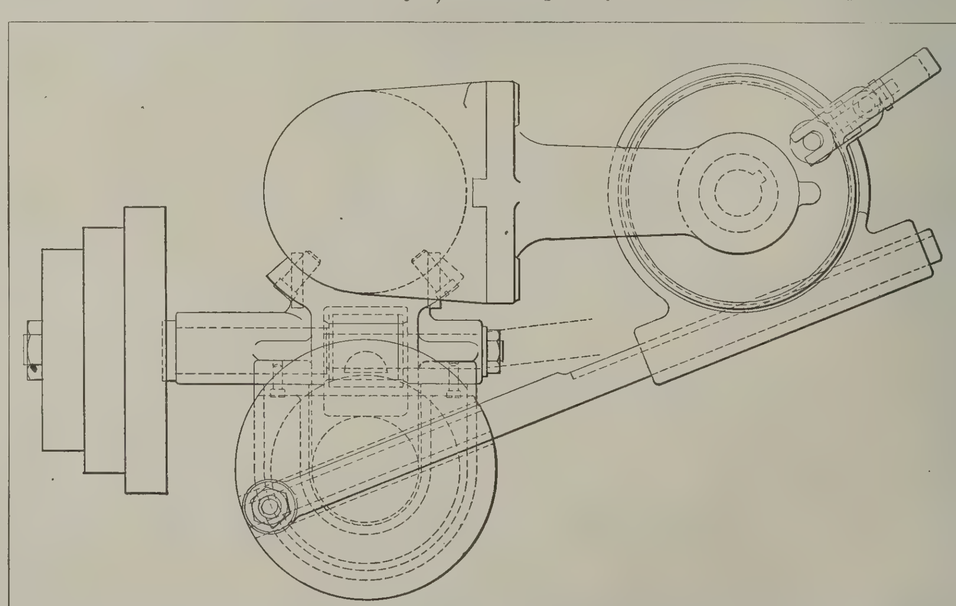

Fig. 6. Mechanism of Power Drive for oscillating Grinder Head

through the spindle to carry the drawback bar, which is fitted with a knob at the outer end that is turned to open or close the chuck by hand. The chuck is prevented from turning, while the work is being put in or taken out, by means of a pin which is carried in the grinder head. As it was not necessary to grind the races to one diameter on the outside, the variation allowed the center of the work to come out of center with the emery wheel. To avoid this trouble, three stop-pins

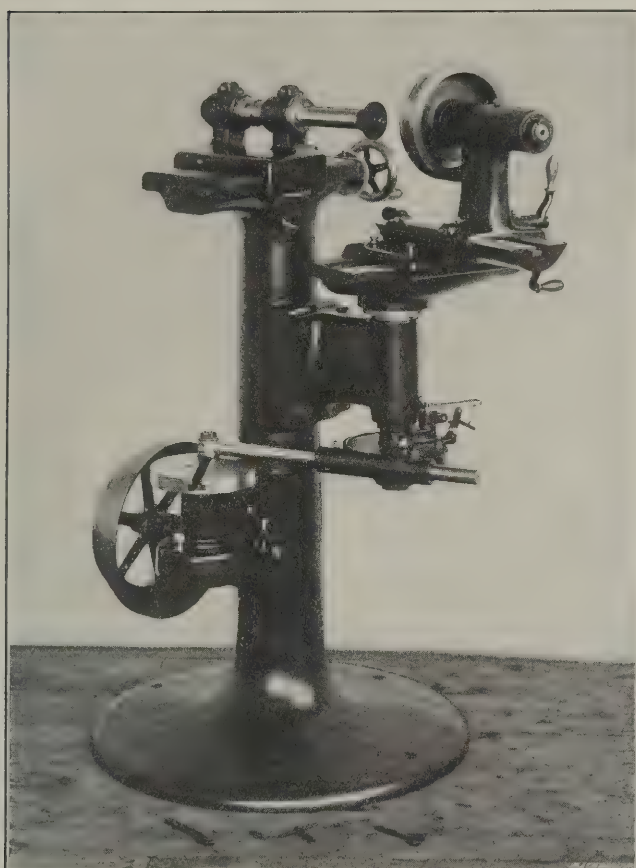

Fig. 7. Type of Machine with Head oscillated by Power

were arranged on the inside of the chuck, the pins being fastened to the head. This allowed the race to come against the pins while the chuck was being closed, thereby holding it central with the emery wheel.

Wet Grinding the Ball Races

Up to this time we had been using a dry wheel, which of course made the work very slow. In order to increase production, the problem of equipping the machines to use a wet wheel was next undertaken, and a solution was finally found in equipping the machines with water guards. It will be

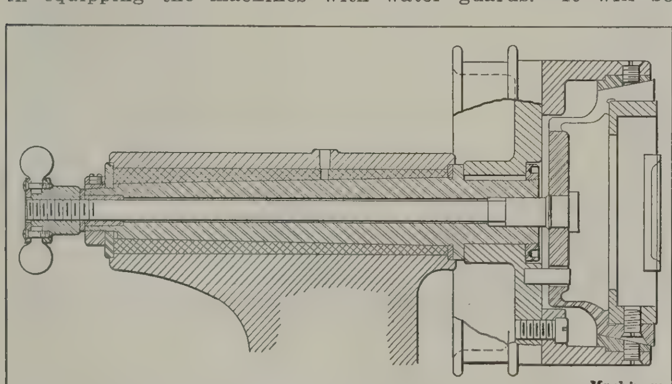

Fig. 8. Improved Type of Grinder Head Chuck

readily understood that this was not an easy matter, as the oscillation of the head caused the water to be thrown in all directions. Fig. 9 illustrates a machine equipped with water guards of the type that was finally devised. The application of wet grinding created a material increase in the amount of work produced. Further increase in this direction arose from equipping the machine with a power feed for the wheel head; this made it possible for one man to run four machines and still produce a very fine grade of work. The power feed for the wheel head was accomplished by means of a regular ratchet wheel and a friction disk which allowed the emery wheel to be fed into the work to a certain point and then stop at any place at which the stop on the friction disk had been set.

The process of grinding the intake groove that is used for assembling the balls in the races requires a great deal of care. This groove must not be too deep or it will permit the balls to jump and catch; if it is too shallow, it will cause the races to be sprung out of shape during the assembling process. The emery wheel used for grinding this groove is slightly larger than the diameter of the balls used in the size of annular bearing race being ground. The depth of the groove is determined by the use of a ball-point micrometer caliper, with which the distance between the bottom of the groove and the outside diameter of the race is measured.

The final operation before assembling consists of polishing or lapping the work. American manufacturers have been considerably behind their European competitors in regard to their polishing methods; it has been the custom to polish only the grooves of bearings made in America, whereas the foreign

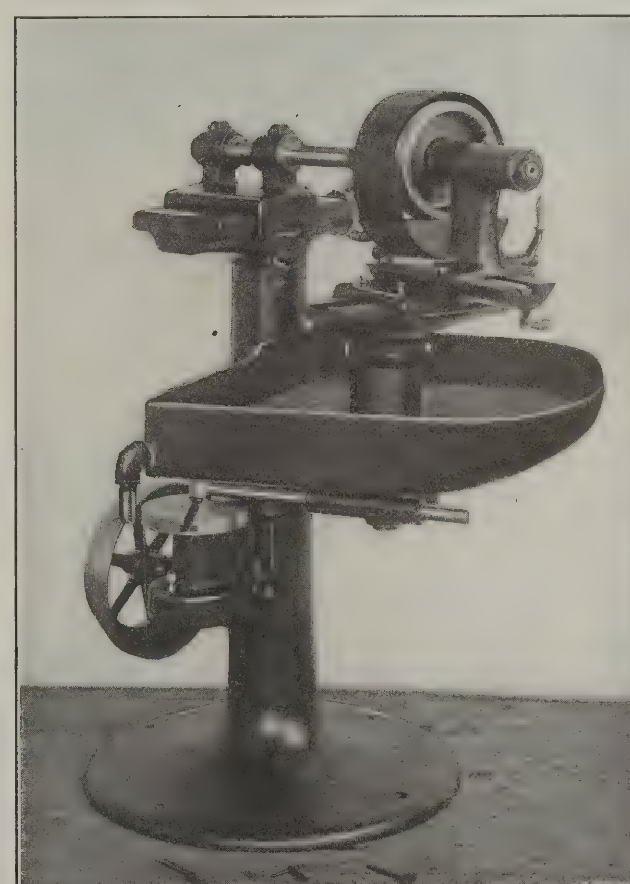

Fig. 9. Type of Water Guards used for Wet Grinding

manufacturer laps the entire surface of the bearing. The finishing operation is conducted by remounting the work in the grinder and using a hard wood wheel covered with crocus, going through the same operation as was formerly followed in grinding the bearing from the rough.

Assembling Bearings

The method of assembling this type of annular ball bearings is a very simple matter. Fig. 10 shows a view in the assembling room which is equipped with tables upon which cast-iron surface plates are mounted. These plates are provided with auxiliary plates of tool steel, which are first hardened and then carefully ground to a perfect surface. Five boxes are located at the rear of each assembling table and each of these boxes contains balls of different sizes. These sizes are as follows: O. K., 0.0005 inch large, 0.0005 inch small, 0.001 inch large, and 0.001 inch small. In assembling a bearing, the assembler takes three balls from one of these boxes and forces them into the bearing by means of the arbor press which is fastened to the table. He then distributes these

balls around the bearing and tests it for the closeness of fit. If the bearing is either too loose or too tight, he forces the balls out and replaces them with the next larger or smaller size, according to the fit that was produced with the first balls tried. This process is repeated if necessary, until the proper size has been secured; the bearing is then filled with balls if it is of the full type, or with one less than the number required to fill the races if a cage is to be used. The foreign manufac-

Fig. 10. Equipment of Room where Annular Bearings are assembled

turers grind all their bearings to one size and consequently they only require an O. K. ball. This is a more expensive process, and to reduce the cost of production American manufacturers have adopted the method previously described. After the assembling process is complete, the assembled bearing is subjected to a final grinding process in order to make the outside of the outer race concentric with the center. As the inner races are a trifle thinner than the outer races, the bearings can be assembled on a gang arbor in the same manner as shown in Fig. 3. In this case, the arbor is of the proper size to fit accurately in the hole in the inner races, and the side faces of the outer races bear against each other. The work is accurately located in this way, and when the grinding operation is finished, the outside of the races is concentric with the center, provided the assembling has been properly done. The finished bearings are tested and then marked to indicate their eccentricity and the degree of side motion that the outer race has when revolved on the inner race. The degree of accuracy required runs from 0.0005 inch to 0.0015 inch according to the diameter of the bearing.

* * *

Steel hardened in oil has not so hard a surface as when hardened in water. This is due to the fact that when water is used for quenching, the cooling of the heated steel takes place at a much more rapid rate than when the cooling is in oil. Experiments show that a piece of steel will cool from 700 to 600 degrees C. (from 1292 to 1112 degrees F.) in five seconds when quenched in pure water, while, when quenched in oil, forty-three seconds was required to cool off the same amount.

* * *

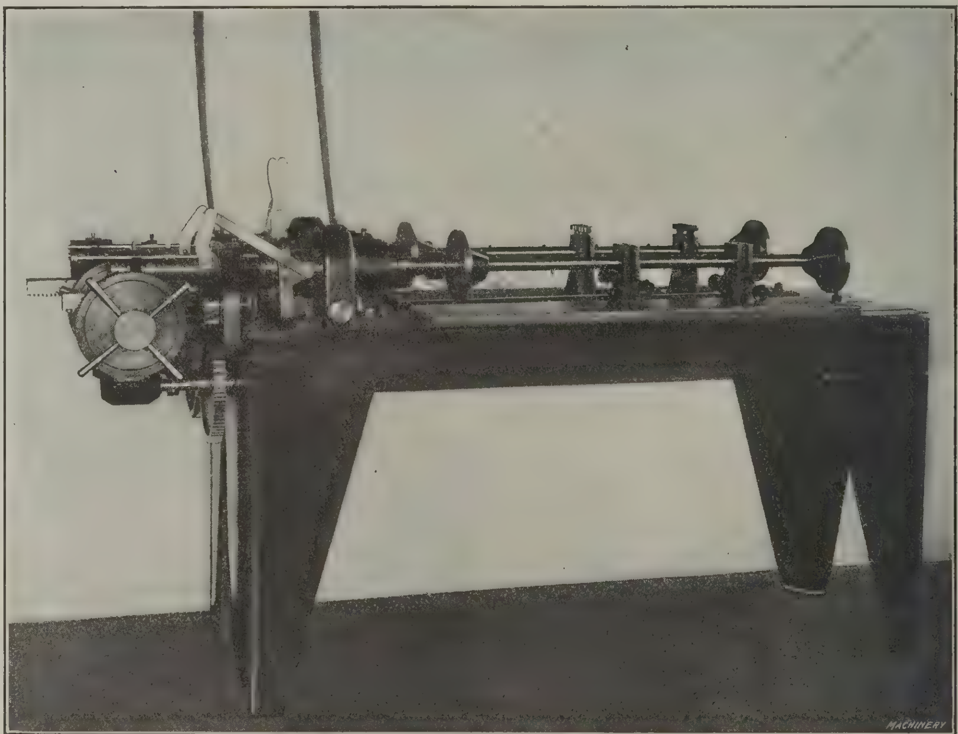
The motor boat *Baby Reliance III* is probably the fastest in the world, having a speed record of 53.8 miles per hour. She is driven by a twelve-cylinder Van Blerck engine fitted with Bosch magnetos.

A DOUBLE-SPINDLE CRANK-CASE BORING MACHINE

A double-spindle horizontal boring machine which will bore a crank-case in two and one-half minutes, when it formerly took fifteen minutes, has just been completed by the tool construction department of the H. H. Franklin Mfg. Co., Syracuse, N. Y. The machine bores two crank-cases at a time; each case has five crankshaft bearings, so that ten bearing holes can be bored at one setting. The operator adjusts one crank-case on the machine and starts boring. While the first crank-case is being bored he adjusts the second, and by the time it is ready, the first crank-case is finished. In this way, continuous operation is obtained.

It will be seen from the illustration that there is an auxiliary table for the different sizes of crank-cases. The work is clamped to the auxiliary table, and two pedestals steady the boring-bars in the center. There are heads at each end of the boring-bars which fit in the ends of the crank-cases, holding them in their true position and practically making each case its own aligning jig. Each boring-bar has five pairs of cutters, which reduce the size of the chips on each cut. These cutters can be adjusted to bore different sized bearings for the different sizes of crank-cases. They bore holes from 1½ inch to 2 inches in diameter.

The boring-bars are driven by a semi-universal joint from the main spindle of the machine. Each spindle is independent and has an independent control. The feed drive is similar to that on any other horizontal boring machine; both heads are driven by worm-wheels from one shaft which runs at 1100 revolutions per minute, and drives the boring-bars at 200 revolutions per minute with a feed of 0.005 inch per revolution. There is a clutch for each main drive and one for each feed; these clutches have an automatic knockout for stopping the spindle and feed. The feed on this machine is obtained by a rack and pinion operating through a train of gearing from the main spindles.



Double-spindle Machine for boring the Crank-cases of Franklin Motor Cars

The machine is designed for one speed and one feed. All bearings have solid bushings to prevent changes in the feed and speed, and to prevent the operator from needlessly adjusting the bearings and getting anything out of order. A safety device on the clutch keeps the spindle from starting unintentionally, thereby protecting the operator from injury while setting the bars or crank-case.

Good lockers for the men should be a part of the equipment of every modern shop and factory.

FORMS OF BABBITTING FIXTURES

BY JOHN A. H. PHILLIPS*

The work of babbitting bearings offers considerable opportunity for the use of different forms of fixtures that are capable of making a material increase in the efficiency with which this operation can be carried on. During the writer's experience, he has had occasion to babbitt a variety of bearings, and in the following article a description is given of the different types of fixtures which he has used.

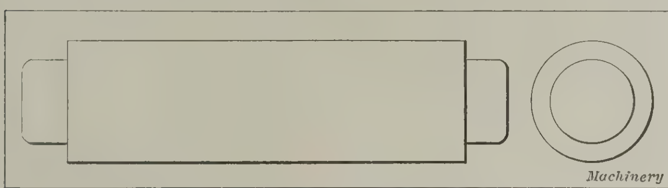

Fig. 1. A Simple Form of Babbitting Mandrel

Fig. 1 shows the most common of all forms of babbitting mandrels. This is merely a piece of shafting of the required size, which is turned down at the ends to fit into the corresponding hole in the supporting plate *A*, shown in Fig. 7. This plate is a piece of cast iron with a number of different sized holes bored in it to fit various sizes of mandrels. The body of the mandrel is turned with a taper of 0.0025 inch per foot of length in order to make it easy for the operator to remove it from the finished bearing. The mandrel is painted with a coat of thin white lead each time it is used.

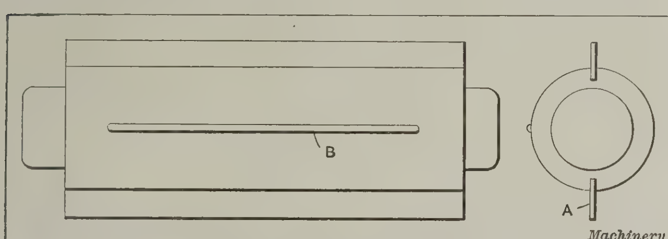

Fig. 2. Mandrel for babbitting Plain Bearing Caps

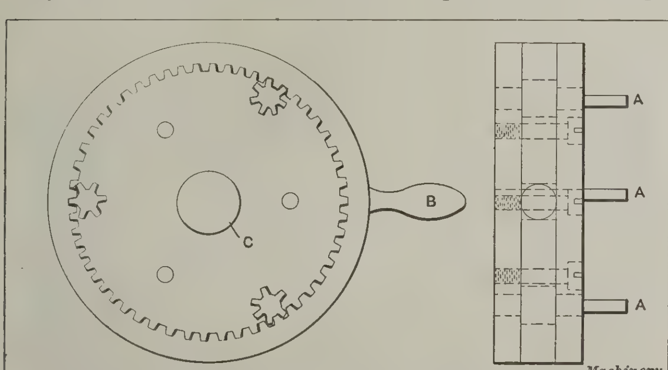

Fig. 3. Fixture used for locating Bearing at Center of Wheel

Fig. 2 shows an arbor for babbitting the cap of a plain bearing. Two thin pieces of steel *A* are inserted in this mandrel, and the space occupied by these strips while babbitting is replaced by liners in the finished bearing. *B* is a projection on the mandrel which forms the oil groove in the bearing, obviating the necessity of cutting it after the babbitting operation has been completed. The fixture shown in Fig. 7 is used for clamping the bearing to the mandrel.

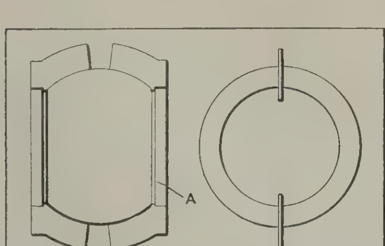

Fig. 4. Fixture for babbitting Spherical Bearings

* Address: 584 S. 4th St., Aurora, Ill.

Fig. 6 shows a rather more complicated form of babbitting mandrel which is used for ring oiling bearings. The two rings *A* are attached to the mandrel and serve to give clearance for the oil rings in the cap. The two small rings *B* are not fastened to the mandrel but are placed in the bearing to prevent the babbitt from running out; the space around these rings is carefully plugged up with putty before the babbitt is poured. Bearings of this type must be babbitted in a horizontal position, the six notches cut in the sheet-steel feathers being used to provide space through which the babbitt is poured.

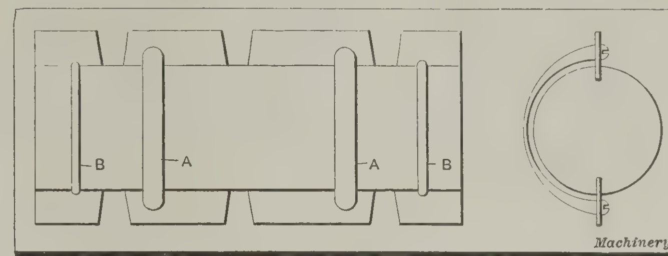

Fig. 6. Mandrel for babbitting Ring Oiling Bearings

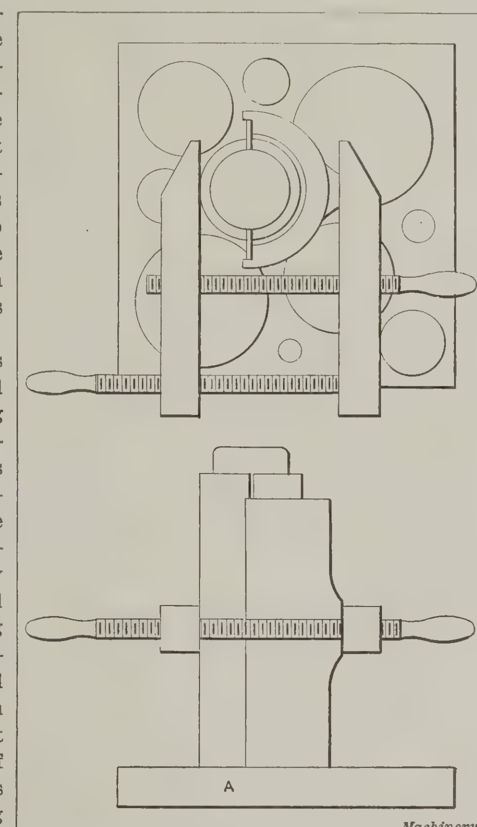

Fig. 7. Fixture for supporting Babbitting Mandrels

Fig. 4 shows a fixture used for babbitting spherical bearings. In this case, the shoulders *A* are made to fit the castings as closely as possible, and any remaining cracks are carefully plugged with putty in order to prevent the escape of the babbitt. This type of bearing is babbitted in halves similarly to the ring oiling bearings, the babbitt being poured through the notches in the thin steel plates, as in the preceding case.

The mandrel shown at *A* in Fig. 5 is used for babbitting the bearing *B*, which is a type that is extensively used on belt conveyors used for handling a variety of loose materials.

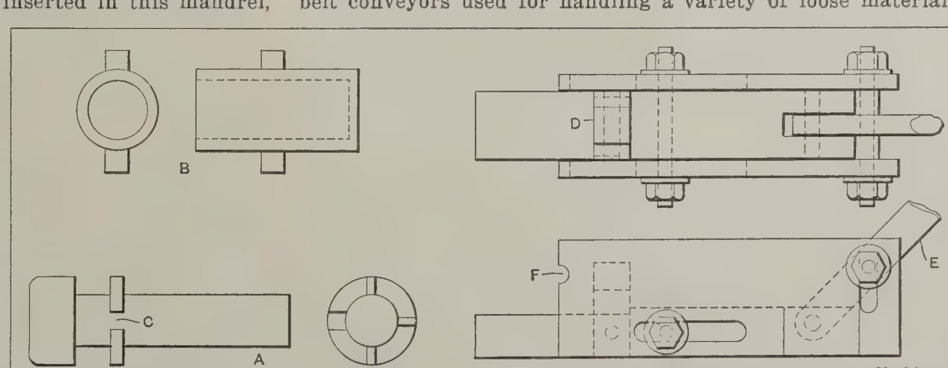

Fig. 5. Mandrel and Fixture used for babbitting Bearing B

The four notches *C* are used as sight holes for centering the mandrel in the bearing; one of these notches is cut larger than the others and is used for pouring the babbitt into the bearing. The jig shown at the right-hand side of the illustration is used for removing the bearing from the mandrel. The

mandrel is placed in the slot *D* with the bearing projecting, and when the lever *E* is brought forward, the notches *F* come into contact with the lugs on the bearing and force it off the mandrel.

Fig. 3 shows a fixture for babbitting cast-iron rollers and wheels. This fixture was designed to provide a means of locating the bearing in the exact center of a wheel; it is made in two halves with teeth cut on the inside of the ring as shown. The three pins *A* are turned eccentric with the pinions of which they are a part, and by swinging the handle *B*, the wheel is accurately centered. A mandrel of the type shown in Fig. 1 is used in connection with this fixture, the mandrel being placed in the central hole *C*.

HOW TO FORGE AND HARDEN A COLD CHISEL

BY C. C. SEMPLE*

Some blacksmiths advocate hammering a cold chisel at a black heat to refine and toughen it. After taking the pains to do this, they will replace the tool in the fire and heat it hotter than it was when they began to refine it, after completing the heavy forging. In such cases, the temperature is often still further increased to secure heat enough to draw the temper. When the required temperature has been reached, the tool is taken from the fire and the cutting end is immersed in the bath, part way up the length of the heat. It is then withdrawn and the blade is next polished with a stick covered with emery or with emery cloth. The blacksmith then waits for the temper to run down from the red hot part above the blade, and when the desired temper shows by color, the whole chisel is immersed in the bath. When sufficiently cool, it is given to the man who is to use it.

By this treatment, the blacksmith has undoubtedly undone a part of the mischief and all of the good—if any—that was produced by his cold hammering. In nine cases out of ten, he has heated the vital part of the tool too hot for good refining in order to make the heavy part hot enough to draw the temper. Any steel that will not stand this treatment and make a good chisel is condemned by him.

Now let us see how a blacksmith who keeps the tools in order for a gang of more than 100 men does such work. He takes a piece of steel of the right length for a chisel, heats it to a bright red heat for one-third of its length, and draws the cutting end down on his steam-hammer to about twice its finishing thickness. This being done, he returns the tool to the fire and reheats it to about the same temperature as before. The work is next taken to the anvil, and by means of a hand-hammer and light sledge in the hands of the helper, the chisel is quickly shaped, with the blade still red-hot, or nearly so, when finished. Instead of resorting to cold hammering to refine the steel, the chisel is again returned to the fire, and a second piece that has been getting warmed up on the side of the fire is also moved to the center at this time. The chisel just forged, when heated to a low red heat, is thrust into the annealing box and left to cool. All the subsequent chisels are treated in the same manner, and if any of them are required for immediate use, the ones that were forged first are selected; if not entirely cold, they are plunged into water to make them so.

The hardening process used for chisels cooled by either of the preceding methods is as follows: A piece of iron is laid across the fire and partially buried. The thin edge of the chisel is laid on this iron and the heat allowed to take hold some distance back and run up to the edge. The blade is then dipped and hardened well up, so that in most cases there is not enough heat left to draw the temper. In hardening chisels by this method, the temper is drawn at a light blue. Chisels hardened and tempered in the manner described are put aside for future use, and it is claimed that if they are allowed to remain several days they are better than when used at once.

It may seem that this is quite a rigmarole for forging and hardening so simple a tool as a cold chisel. The question arises, does the end justify the means? The fact that this blacksmith keeps the tools in shape for more than 100 men, and that every one of these men will swear that the tools are the best he ever used in any shop where he has worked, leads to the supposition that there is something in it.

This same method of treatment may be safely applied to all forged tools, so far as omitting the cold hammering and heating of the larger parts to draw the temper is concerned. It is an established fact that many of the high-carbon and alloy steels require reheating to relieve the forging strains and tnat they are improved by being reheated and allowed to cool slowly after forging. It is also an established fact that these steels are ruined if they are hammered at any temperature much below a red heat. The inference is plain that the steel made nowadays does not require the old time blister-steel treatment, and that it will not stand it and yield the best results. The most economical steels to use are now made in such a way that they need no refining on the part of the blacksmith. You will get less hardening cracks by hardening in saturated brine than by hardening in water, but in any case the piece must be kept moving in the hardening fluid. These notes were supplied to the writer by the manufacturer of a well known and extensively used brand of Swedish steel (Fagersta), but the method is equally applicable to all high-grade steels.

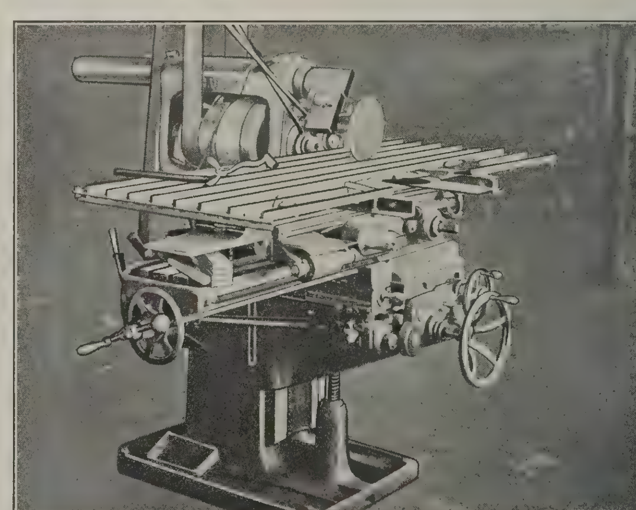
A COMBINATION OF GRINDER AND MILLING MACHINE

BY S. A. MCDONALD*

The accompanying illustration shows a way of combining two machines to perform an operation on a piece of work which could not be handled otherwise with the average small shop equipment. The work done consisted of a special machine table 5 feet long and 2 feet 2 inches wide, to which were fastened a series of rows of ½ by ¾-inch cold-rolled steel bars. Five of these guide bars were to be parallel within a variation of less than 0.005 inch for their full length; hence, it was considered necessary to grind them.



A Combination of Grinder and Milling Machine

This was a job for a large plain grinder, but, as such a machine was not available, the following method was resorted to:

The platen and grinder bed of a No. 2 Walker grinder were placed on the table of a No. 14A Garvin milling machine, the grinder bed being clamped to the table of the milling machine, and the table to be machined bolted to the grinder platen. By this arrangement the combined travel of the grinder and milling machine tables was sufficient to cover the work. A lathe grinding attachment was fastened to the overhanging arm of the milling machine. This attachment was belted to a pulley on the lineshaft. By shifting the arm in or out, the emery wheel was set to approximately the right position, and the arm clamped. The final adjustment was then made by the transverse feed of the milling machine. The grinding was done with the side of the wheel and a very smooth finish was obtained, well within the limits of accuracy required.

DYNAMICS OF GAS ENGINE CAMS—2

AN INVESTIGATION INTO THE RELATIVE MERITS OF DIFFERENT TYPES OF CAMS

BY M. TERRY*

In the previous installment of this article an analysis was made of a tangential cam, such as is commonly used in gas engine design for automobile engines. In the present installment, it is proposed to make a similar investigation with relation to a uniformly accelerated and retarded motion cam, in order to definitely determine if the latter possesses advantages over the tangential cam.

In comparing different types of cams, or even cams of the same type, we must make them alike in all respects but the one we wish to investigate. It is evidently impossible to draw any conclusions by comparing cams of different lifts and base circles and driven at different speeds, or having followers of different diameters, possessing different clearances and producing different timing of valves.

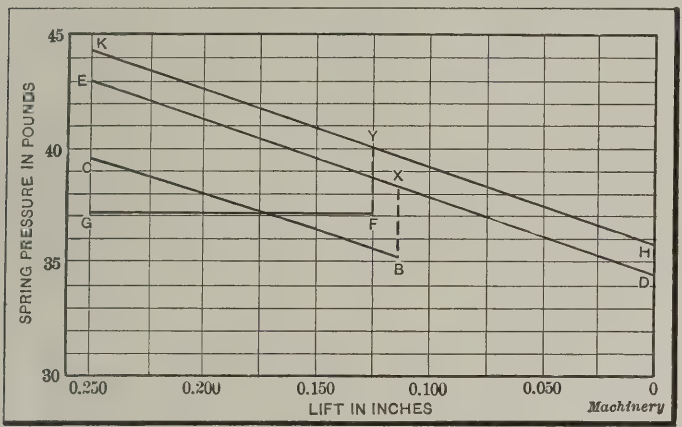

Fig. 14. Spring Pressure Diagram for Tangential and Uniformly Accelerated Motion Cams

Since the object of our investigation is to find out which shape of the two cams is more suitable in a dynamic respect, we shall make our uniformly accelerated aand retarded motion cam identical with the tangential cam discussed in the first installment. In other words, our new cam must comply with the following requirements:

Base circle = 1.000 inch in diameter.
Roller circle = 1.000 inch in diameter.
Lift = ¼ inch. Full lift must be attained in the same length of time, *i. e.*, in 53 degrees of the angular motion of the cam.
Weight of reciprocating parts = 1.6 pound.
The same rotary speed, *i. e.*, the camshaft turns through 1 degree in 1/5000 second.
The same timing, which, so far as individual cams are concerned, means that the exhaust and inlet valves should stay open 110 degrees and 100 degrees, respectively.
The same amount of clearance between the valve lifter and the valve stem.

The last item, it will be noted, does not call for the 5 degrees clearance angle assumed with the tangential cam, and the reason for this will be shown presently.

Clearance and Clearance Angle

In the early part of the first installment reasons were given for the necessity of clearance whenever the poppet type of valve is used. The amount of clearance given is, in general, arbitrary, and with different manufacturers it varies from 0.004 to 0.010 inch. With the valve gear arrangement shown in Fig. 15 a backlash of, say 0.006 inch is obtained by inserting a steel gage 0.006 inch thick between A and B; the timing gears are then adjusted so as to secure the timing originally intended for that motor. When this last object is attained with a reasonable degree of accuracy the screw B is locked securely in place, and only a slight pull should be sufficient to remove the gage.

It is clear, then, that the valve lift is equal to the cam lift less the clearance, and that the follower would rise the amount of backlash before the valve proper is started on its upward journey. This loss in valve lift is generally neglected, but its effect on valve timing is universally recognized.

* Address: 910 E. Washington St., Ann Arbor, Mich.

In Fig. 16, O is the center of the tangential exhaust cam which turns counter-clockwise. The cam and its follower are shown in the position where the latter starts on its upward motion. As before, assume that the cam is stationary and that the roller moves to the right; its center C will describe a straight line CC_2, and in doing so the distance between O and C will increase. When such a point, C_1, is reached that $OC_1 - OC$ equals the backlash, the valve will begin to open. The angle COC_1 is known as the clearance angle or the angle of backlash.

$$\cos COC_1 = \frac{OC}{OC_1} = \frac{OC}{OC + \text{backlash}}$$

In general, the amount of backlash is assumed first and the angle of clearance is determined afterwards. Since, however, in the case analyzed in the previous installment of this article we have assumed the angle of backlash to be 5 degrees, our first problem is to determine the amount of clearance corresponding to 5 degrees.

$$\cos 5 \text{ deg.} = \frac{1}{1 + x}, \text{ or } x = 0.00382 \text{ in.}$$

Our next problem is to determine the clearance angle of the uniformly accelerated and retarded motion cam corresponding to this amount of backlash, *i. e.*, 0.00382 inch.

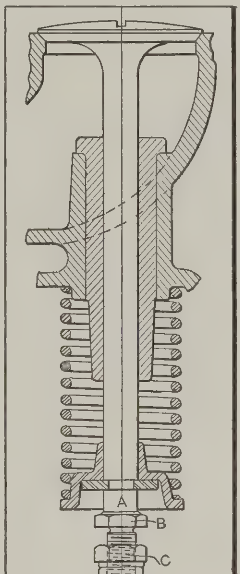

Fig. 15. Valve Mechanism

Uniformly Accelerated and Retarded Motion Cam

Almost every text-book on mechanisms mentions the uniformly accelerated motion type of cam. In our case it would be a cam so shaped as to impart to the roller center a uniformly accelerated motion during the first half of the lift, and a uniformly retarded motion during the second half.

If A = acceleration per second, in feet per second (constant),
t = time in seconds,
v = velocity in feet per second,
S = lift in feet,

Then

$$v = A \times t \qquad (1)$$
$$S = \tfrac{1}{2}At^2 \qquad (2)$$

These equations can be applied only within the limits of one-half the lift. A is unknown for the present, but its value can be readily determined from the last equation. In the present case:

S = 1/8 inch, or 1/96 foot,
$t = 26\tfrac{1}{2} \times 1/5000 = 0.0053$ second,

$$A = \frac{2S}{t^2} = 741\ 2/3 \text{ feet per second per second.}$$

To find the clearance angle x corresponding to a backlash of 0.00382 inch:

$$t^2 = \frac{2S}{A} = \frac{2 \times 0.00382 \times 1/12}{741\ 2/3}$$

from which we find $t = 0.000926$ second. But

$$t = x \times \frac{1}{5000},$$

from which $x = 5000 \times t = 5000 \times 0.000926 = 4.63$ degrees, or 4 degrees 38 minutes.

The clearance angle of the uniformly accelerated and retarded motion cam being equal to 4 degrees 38 minutes, the

total angle of the exhaust cam = 110 deg. + 2 × (4 deg. 38 min.) = 110 deg. + 9 deg. 16 min. = 119 degrees 16 minutes (see Fig. 17), and the total angle of the inlet cam = 109 degrees 16 minutes.

The cam shown in Fig. 17 is what may be termed the equivalent of the tangential cam, Figs. 9 and 10, previous installment.

In order to plot an accurate lift curve (Fig. 18), as well as to draw the contour of our new cam (Fig. 17) we shall make a table of lifts for each degree of the cam.

TABLE IV. ANALYSIS OF UNIFORMLY ACCELERATED MOTION CAM

α	a	L	α	a	L
1	0.000356	0.000178	15	0.000356	0.040050
2	0.000356	0.000712	16	0.000356	0.045568
3	0.000356	0.001602	17	0.000356	0.051442
4	0.000356	0.002848	18	0.000356	0.057672
5	0.000356	0.004450	19	0.000356	0.064258
6	0.000356	0.006408	20	0.000356	0.071200
7	0.000356	0.008722	21	0.000356	0.078498
8	0.000356	0.011392	22	0.000356	0.086152
9	0.000356	0.014418	23	0.000356	0.094162
10	0.000356	0.017800	24	0.000356	0.102528
11	0.000356	0.021538	25	0.000356	0.111250
12	0.000356	0.025632	26	0.000356	0.120328
13	0.000356	0.030082	26.5	0.000356	0.125000
14	0.000356	0.034888	..	....	....

Equation (2) may be put in the form:

$$L = \tfrac{1}{2} a \alpha^2$$

where L is the lift of the cam follower in inches, α is the cam angle in degrees, and a the acceleration per degree, in inches per degree; this acceleration is, of course, constant and can be readily determined:

$$a = \frac{2L}{\alpha^2} = \frac{2 \times 0.125}{(26.5)^2} = 0.000356 \text{ inch.}$$

(Since full lift is attained in 53 degrees, a lift of 0.125 inch corresponds to an angular motion of 26½ degrees.)

Knowing now the value of a, and by assigning various values to α in the equation just given, we can determine the lift or position of the roller center for every degree of the cam. This is done and the results are compiled as shown in Table IV. With the help of this table we can now plot a complete lift curve, since the latter is symmetrical both with respect to XX and YY, Fig. 18.

Again, with O as the center of our cam (Fig. 17) strike two arcs AA of 1 inch radius and CC of 1¼ inch radius, and from intersections of these arcs with the radial lines of the cam lay off proper lengths as indicated in the third column, Table IV. A line through the points thus obtained represents the path of the roller center; if from these points as centers we strike a number of arcs the radii of which are equal to the radius of the roller, the curve drawn tangent to these arcs will give us the contour of the cam.

The Valve Spring

In the previous installment we have fully discussed the functions of the cam and of the valve spring, and the conclusions there arrived at hold good for the uniformly accelerated and retarded motion cam. It remains now to select a suitable valve spring. If

T = spring pressure in pounds,

A = acceleration per second in feet per second required by the cam,

m = total mass of the reciprocating parts of the valve gear plus one-half the mass of the spring proper, we have:

$$T = m \times A = \frac{A \times 1.6}{32} = \frac{742 \times 1.6}{32} = 37.1 \text{ pounds.}$$

Since A is constant, 37.1 pounds of pressure is all that is required of the spring at any point from one-half to full lift of the cam. In other words, the ideal spring for a uniform motion cam is the one whose stress-strain curve is a horizontal line. This, of course, is an impossibility, for within its elastic limit any spring will exert pressure directly proportional to its distortion.

In Fig. 14 (reproduced from the previous installment) the line FG represents the spring pressure required by the uniformly accelerated and retarded motion cam. If we wish to use the same spring that we have designed for the tangential cam, and give it the same excess of pressure at F as it has anywhere between the lines BC and DE, we shall obtain HK for our actual spring pressure line. This would give us a spring, the initial and final pressures of which are 35.8 pounds and 44.4 pounds, respectively. In other words, a greater spring pressure is required for the uniformly accelerated and retarded cam.

Our conclusions in regard to the relative stiffness of springs required for the two cams are substantiated by an actual test of two engines identical in every respect but for the shape of their timing cams. The two engines were originally equipped with identical valve springs. The follower of the uniformly accelerated motion cam developed a tendency to "jump" the cam at from about 2100 to 2200 R. P. M. of the engine; the follower of the tangential cam showed signs of the same tendency when the engine speed exceeded 2400 R. P. M. The "jumping speed" of the first follower was raised to about 2500 R. P. M. by equipping its motor with additional valve springs.

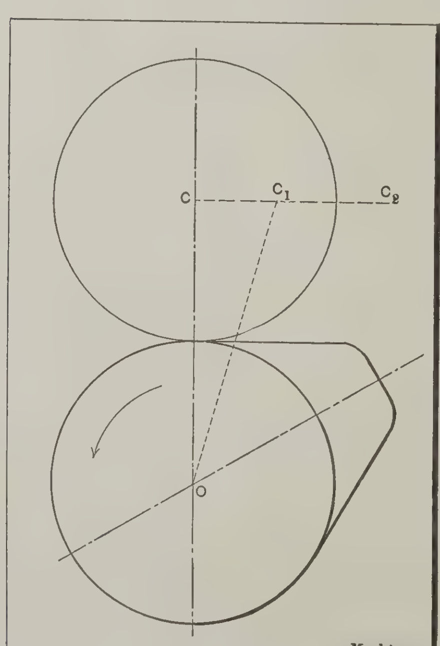

Fig. 16. Relation between Clearance and Clearance Angle

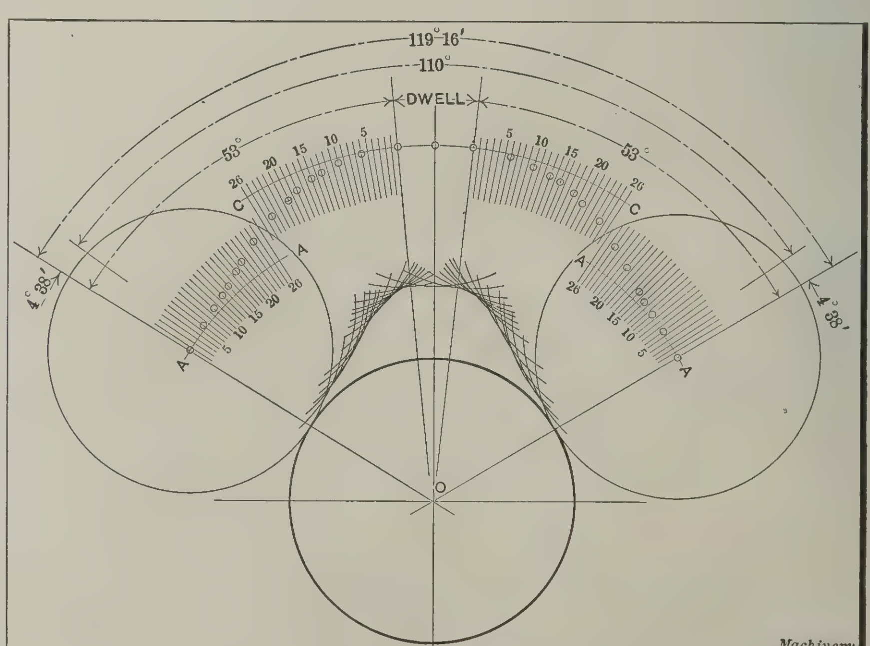

Fig. 17. Lay-out of a Uniformly Accelerated and Retarded Motion Cam

The two motors were built for racing purposes, and if the writer remembers correctly, the valve lift was 7/16 inch (unusually high for automobile engines); the weight of reciprocating parts of the valve gear was 2.7 pounds, and the spring pressures were 175 pounds for the tangential and about 200 pounds for the uniformly accelerated motion cam. The experiment referred to took place over two years ago, and its results were contrary to the expectations of all concerned, for the prevailing opinion among designers is that of the two cams it is the tangential one that requires the stronger spring. To quote Mr. P. M. Heldt (*Horseless Age*, July 5, 1911, pages 4 and 5): "* * * this computation is based on supposition that acceleration and deceleration of the valve are uniform. With a tangential cam this is not the case, and the spring should then be made slightly stronger."

The author takes exception to this opinion. A glance at Fig. 14 will suffice to convince anyone who is even slightly familiar with mechanics. Assume a multiple cylinder engine equipped with cams of both types; the valve springs are all alike, their pressure line being represented by *DE*. As the speed of the engine rises above the assumed maximum, the lines *BC* and *FG* would rise parallel to themselves; *DE* would, of course, remain stationary, for the spring pressure is independent of the engine speed. It is clear, then, that *FG* would be the first line to cross *DE*, or to put it in other words, the uniformly accelerated motion cam would be the first one to exceed the capacity of the spring.

It would not be out of place here to mention the fact that if one is very anxious to prove the contention that a tangential cam requires more spring pressure than one with a uniformly accelerated motion outline, he can easily do so by "juggling"

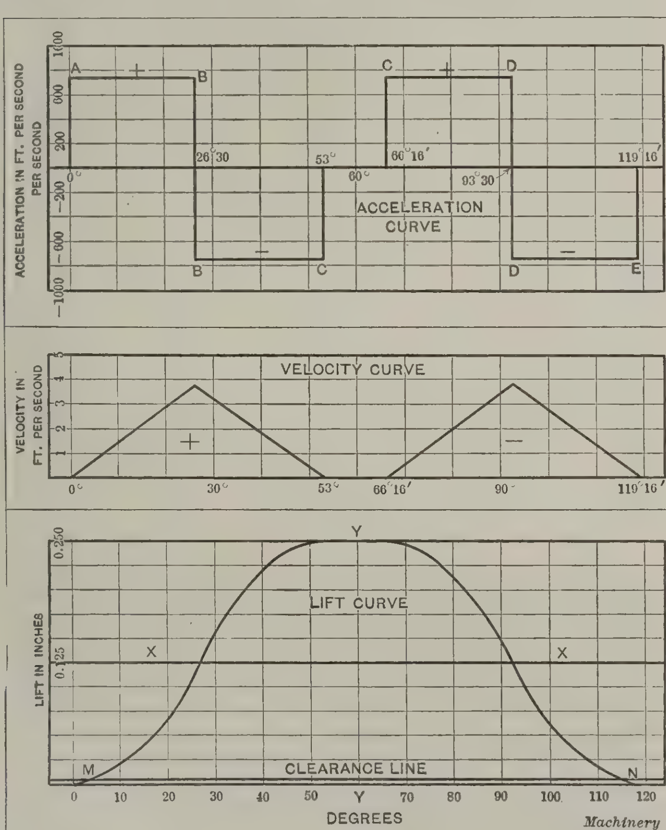

Fig. 18. Acceleration, Velocity and Lift Curves for a Uniformly Accelerated and Retarded Motion Cam

with the former. For instance, he can take the cam described in the first installment and give it a fillet of 1/16 inch radius instead of ⅛ inch. This will put a heavier duty on the spring, requiring it to perform the work of retardation and of acceleration in less time; but in this respect our comparison of the two types of cams has been absolutely fair, for not only was the total time required to lift the valve to its full height the same in both cases, but in each case the time was equally divided between acceleration and retardation, and that is as far as one can go in making the two cams alike. The only difference between them lies in the nature of their accelerations: it is constant in one and variable in the other; and, as has already been proved, in the case of the tangential cam it varies in such a manner as to favor the spring.

Origin of Noise

In a lecture delivered before the automobile class of the West Side Y. M. C. A., New York, Mr. C. E. Reddig, engineer of the United States Motor Co., speaking on the Silent-Knight motor, said, in part:

"The Knight engine is not different from standard engines, except in its valves; the cycles are performed in the usual manner, the gas is drawn from the carbureter, is compressed,

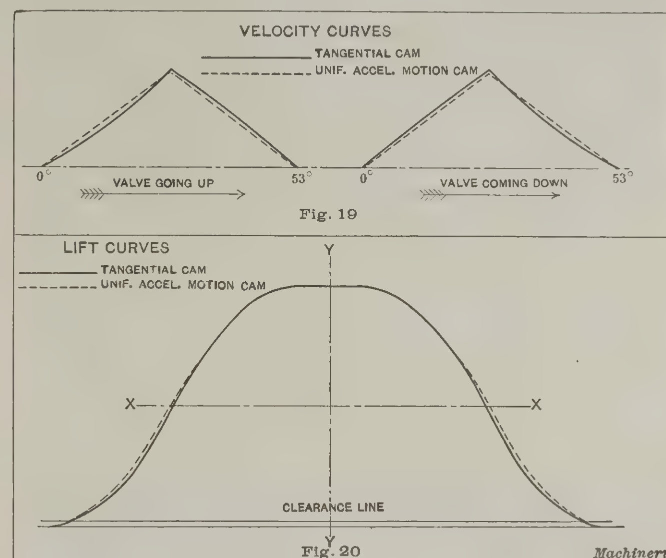

Fig. 19. Comparison of Velocity Curves. Fig. 20. Comparison of Lift Curves

combustion takes place, and it exhausts, in the same manner as in any of the four-stroke cycle engines.

"The changes which in the Knight engine constitute the great improvement over ordinary types of engines are the silent, tremorless, sliding sleeves working away perfectly without care or attention. They make no noise, for they strike nothing. They cause no vibration."

Indeed, they make no noise, for they strike nothing. Not so with the poppet valve. In what follows we shall limit our discussion to the type of mechanism shown in Fig. 15. The complete lift curves, Figs. 12 and 18, represent the motion of the follower and of all the parts rigidly connected to it. The motion of the valve proper, while following along the same curve, does not commence until after the cam follower rises the amount of the backlash. In other words, the valve motion begins at *M*, the point of intersection of the lift curve with the clearance line; likewise it ceases at *N*.

If at *M* and *N* we erect ordinates until they intersect the velocity curve, the cause of noise will become apparent: 1. The cam follower possesses a definite velocity at the instant it comes in contact with the valve stem. 2. The valve possesses the same velocity when its head comes in contact with the valve seat. Whenever two bodies possessing different velocities come in contact, impact takes place; and in the case of poppet valve engines, there are two impacts per cycle for each valve in the engine.

The impact due to the valve striking its seat can be most readily analyzed. Owing to the rigidity of construction of both the valve head and the cylinder casting, practically no deformation of either can take place after the impact, and, consequently the velocity of the valve must vanish almost instantly. At the instant the valve strikes its seat, the former, owing to its velocity, possesses a definite amount of kinetic energy, the value of which is $\frac{1}{2}mV^2$, where m is the combined mass of the valve, and of all the parts attached to it, plus one-half the mass of the valve spring, and V is the velocity of the valve at the instant it strikes the seat. Since, after the impact, V vanishes almost instantly, the kinetic energy of the valve must also completely disappear. However, energy cannot be created nor destroyed, and the kinetic energy of the valve merely undergoes a transformation and reappears in other forms of energy, namely: heat and sound.

In just what proportion the kinetic energy resolves itself

into the above two forms is, of course, impossible to tell. Simple observation seems to indicate that the pounding noise increases very rapidly with the speed of the engine, and we are justified in making the assumption that, at all ordinary engine speeds, noise constitutes a constant percentage of the kinetic energy of the valve at the moment of impact. We can write then:

$$\text{Noise} = c \times \tfrac{1}{2} m V^2 = K V^2$$

where K is a constant.

This assumption is very useful for the purpose of comparing the pounding action of valves due to different cams.

Tangential vs. Uniformly Accelerated Motion Cams

Sub-figures ($_1$) refer to uniformly accelerated motion cam, and sub-figures ($_2$) to the tangential cam.

Let S_1 = backlash in feet,

A_1 = acceleration per second, in feet per second,

V_1 = velocity of the valve in feet per second at the moment of impact,

β_1 = angle of backlash = 4 deg. 38 min., or 4.63 degrees,

t_1 = time in seconds required for the cam to turn through the angle of backlash $= \beta_1 \times 1/5000$.

S_2 = backlash in feet,

A_2 = average acceleration per second, in feet per second during the angle of backlash,

V_2 = velocity of the valve in feet per second at the moment of impact,

β_2 = angle of backlash = 5 degrees (see previous installment),

t_2 = time in seconds required for the cam to turn through the angle of backlash $= \beta_2 \times 1/5000$.

Then

$$V_1 = A_1 t_1 \qquad (3)$$

$$V_2 = A_2 t_2 \qquad (4)$$

$$S_1 = \tfrac{1}{2} A_1 t_1^2 \qquad (5)$$

$$S_2 = \tfrac{1}{2} A_2 t_2^2 \qquad (6)$$

Substituting (3) and (4) in (5) and (6), respectively, we obtain:

$$S_1 = \tfrac{1}{2} V_1 t_1 \qquad (7)$$

$$S_2 = \tfrac{1}{2} V_2 t_2 \qquad (8)$$

But $S_1 = S_2$, since the amount of backlash allowed was the same in both cases. Hence $\tfrac{1}{2} V_1 t_1 = \tfrac{1}{2} V_2 t_2$ (9)

and

$$\frac{V_1}{V_2} = \frac{t_2}{t_1} \qquad (10)$$

Now since $t_1 = \beta_1 \times 1/5000$ and $t_2 = \beta_2 \times 1/5000$,

$$\frac{t_2}{t_1} = \frac{\beta_2}{\beta_1} \qquad (11)$$

Substituting (11) in (10):

$$\frac{V_1}{V_2} = \frac{\beta_2}{\beta_1} = \frac{5}{4.63} \qquad (12)$$

Now, then, everything else being equal, we can write:

$$\frac{\text{Noise due to the uniformly accelerated motion cam}}{\text{Noise due to the tangential cam}} = \frac{V_1^2}{V_2^2} = \frac{\beta_2^2}{\beta_1^2} = \frac{5^2}{4.63^2} = 1.16,$$

or 16 per cent greater.

The fact that in the early stages of opening and the late stages of closing, the valve velocity due to the uniformly accelerated motion cam is greater than that due to the tangential cam can be shown graphically by superimposing the velocity curves of the two cams. (See Fig. 19.)

Lift Curves Compared

Our study of the two cams would remain incomplete if we failed to compare their lift curves. As a matter of fact, these are the only curves that the majority of designers ever take pains to construct and to compare. The object of their comparison, however, has nothing to do with the dynamics of the cams themselves.

In Fig. 21 is shown what is known as a flat-seated valve. The effective area for the passage of gases is that of a cylindrical surface whose diameter is D and whose height is Y. This area is equal to πDY, where π and D are constants, and Y at any instant is the actual rise of the valve. When a cone-seated valve is used, the relation between the effective area-opening and the valve lift is somewhat more complicated.

It is the aim of every designer to provide as large gas passages as possible in order to increase the volumetric efficiency, and—along with it—the output of his engine. At any instant, then, the lift regulates the amount of charge admitted, and, thus, the former can graphically represent the latter. The total charge taken in during the suction stroke of the engine, and consequently, the output of the latter can be represented by the lift-integral, *i. e.*, by the area bounded by the lift curve and the clearance line.

It is clear, then, that the output of the two identical engines equipped with different cams would be approximately proportional to their lift-integrals, and it is for the sake of

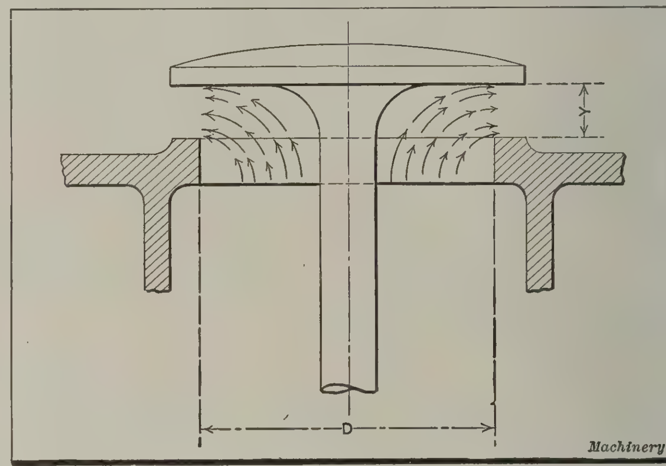

Fig. 21. Relation between Lift and Discharge Area

comparison that we have superimposed the lift curves of our two cams, as shown in Fig. 20. The advantage is in favor of the uniformly accelerated motion cam, but the amount of this advantage is very slight, as anyone can see at a glance.

To sum up our results:

1. A tangential cam requires less spring pressure than a uniformly accelerated and retarded motion cam.
2. It produces less noise.
3. It can be manufactured more cheaply and accurately.
4. The indicated horsepower of the engine would, in all probability, be the same, no matter which type of cam were employed.

OIL-MIXED PORTLAND CEMENT CONCRETE

A serious drawback to the general use of concrete for tanks, cisterns, house walls, cellars, etc., is its permeability to moisture. A concrete cistern, unless specially treated, is likely to be leaky, and even if leakage is not serious, it is usually objectionable on account of the dampness resulting from it. Concrete block houses are often damp and unhealthful. Several formulas for making concrete waterproof have been successfully used but some of them are too expensive for general application. One of the simplest, cheapest and most effective yet found is that developed by the U. S. Geological Survey in the office of public roads by Mr. L. W. Page. Mr. Page found that a heavy residual mineral oil of 0.93 specific gravity, mixed with Portland cement, makes it waterproof and does not weaken when the concrete consists of, say, cement, one part, sand, three parts, and oil not more than ten per cent by weight of the cement. Concrete mixed with oil requires about fifty per cent longer time to set hard, and the compressive strength is slightly decreased, but not seriously. The bond or grip of oil concrete on steel is much decreased when plain bars are used, but formed bars, wire mesh or expanded metal act as effectively in it as in ordinary concrete.

* * *

It has hitherto been believed that pitchblende, the mineral containing the largest amount of radium of any mineral known, was principally to be found in Austria. It is now stated, however, that this mineral is found in even greater quantities in one of the northern provinces of Sweden, and that it is only a question of time when these deposits will be worked for obtaining the radium contained in them.

MODERN METHODS OF A PRESS WORKING PLANT

DESCRIBING WORK DONE BY THE WORCESTER PRESSED STEEL CO.

BY CHESTER L. LUCAS*

Nestling under a hillside at Greendale, one of the pretty suburbs of Worcester, Mass., are the works of the Worcester Pressed Steel Co., an "aviator's view" of part of which is presented in Fig. 1. The buildings of the plant embrace the main press working factory; the foundry for making special tool castings for dies, die beds, etc.; a new building for pickling, with ventilated roof 45 feet high; the rolling mill for cold-rolling strip steel; the acetylene gas generating house; the annealing and casehardening building; the storage and shipping building; the office building and the power house. The business was established in 1883 under the name of the Worcester Ferrule & Mfg. Co., at which time it occupied 7000 square feet of floor space and employed 20 hands. At the present time the plant covers 70,000 square feet of floor space and gives employment to 250 men.

Fig. 1. Aviator's View of Worcester Pressed Steel Co.'s Plant

This manufactory specializes in cold drawing, pressing, forming and stamping shapes to order from steel, brass, aluminum and other sheet metals.

Rolling the Metal

On account of the accuracy and various thicknesses of steel required for pressed and seamless drawn metal products, as well as the necessity for having sheet metal with highly finished surfaces, this company maintains a pickling and rolling department of its own, for cold-rolling the steel to its finished gage. A section of this department is shown in Fig. 2. On the two machines shown, the steel rolls themselves are 12 inches in diameter. During the rolling operation, the rolls are kept flooded with oil. To furnish adequate facilities for this work, a new building 70 feet by 110 feet has just been completed and equipped with most modern vats, cranes and appliances. Work has also been started on another new cold-rolling mill, 150 feet by 100 feet in size and of steel and glass construction. A fireproof addition to the main press shop, 90 feet by 100 feet in size, is now being erected.

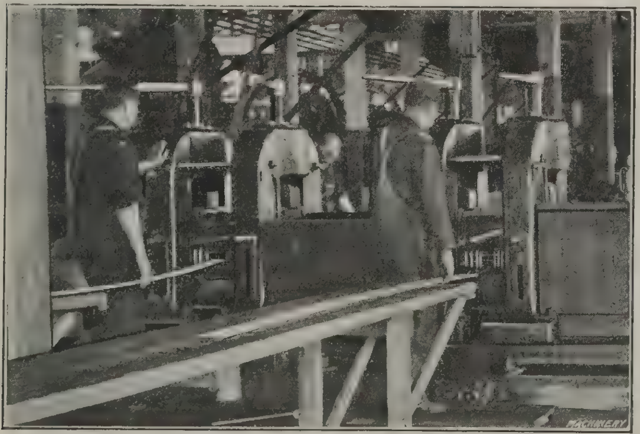

Fig. 2. A Corner of the Sheet Metal Rolling Department

Making Radiator Fans

One of the interesting jobs of press work done in these works is the making of a one-piece steel fan for an automobile radiator. These fans are 14 and 16 inches in diameter, made of cold-rolled sheet steel 0.035 inch thick, and reinforced at the edge by an enclosed wire ring which stiffens the entire fan. The different stages in making the fan may be seen by referring to Fig. 3. Commencing with the blank at the left-hand upper corner, these pieces represent the work done: blanking; flanging edge; closing in preparatory to wiring; closing the wire in position; piercing between the blades; shaping the blades; electrically welding the spider and hub; and piercing the rivet holes in the hub.

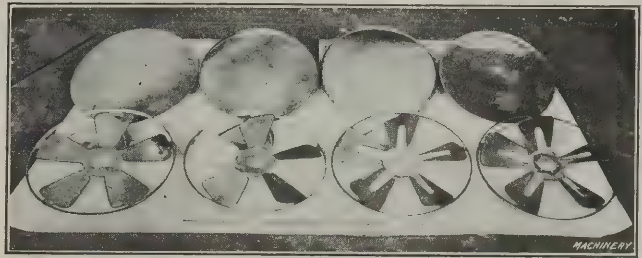

Fig. 3. Evolution of a Radiator Fan

The blanking, flanging and closing-in operations are ordinary jobs of press working. The welding operation which connects the spider with the blades of the fan is performed upon a National electric welding machine, known as a spot welder. This operation is shown in Fig. 4. A helper clamps a spider upon the fan with a simple fixture, which centers the hole in the spider with the opening in the fan and holds both parts securely in place. This being done, the welding machine operator spot-welds an arm of the spider to a corresponding blade on the fan, hands it back to the helper, who has, in the meantime, prepared another fan and spider for welding. The helper now removes the fixture from the fan and the welder completes the work on the other blades, while another fan is being placed in the fixture. There are three welds to each blade and fifteen welds to a fan. A welder and a helper will

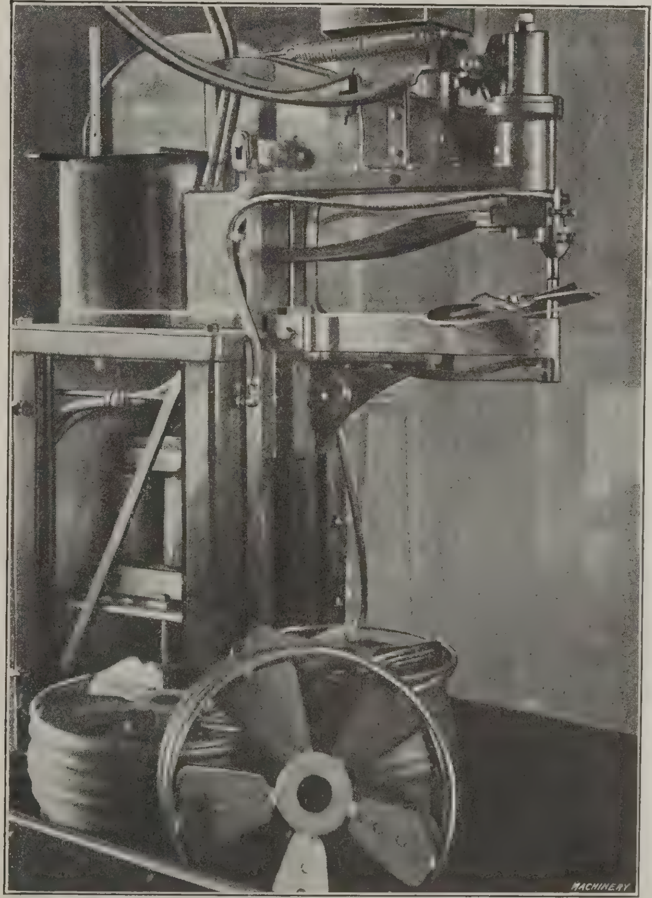

Fig. 4. Welding Fan Blades on a National Spot Welder

* Associate Editor of MACHINERY.

turn out about 400 fans per day of ten hours, which makes a total of about 6000 welds per day. There are four of these machines in this department.

Cold Forging

A somewhat unusual branch of press work was developed and is followed to a considerable extent in this shop, *viz:* cold forging. Cold forging is the name commonly applied to the process of producing sheet metal shapes or pieces having raised bosses or projections upon their surfaces. Some typical examples of this class of work, as well as the steps followed in making them, are shown in Fig. 5. Such work requires powerful presses, the samples shown being made in a heavy, 1000 ton capacity knuckle-joint, Toledo press, which is shown in Fig. 6. Needless to say, such work requires dies that will stand this heavy pressure, and Vulcan steel is one of the steels which has proved very satisfactory for these dies. In the making of pieces of this nature, blanks are used which are oftentimes waste punchings from the production of other pieces. These pieces are struck between the dies, which, except for the depressions for forming the bosses or panels, are flat. Such being the case, the result of this cold forging operation leaves the work in the condition shown by the central pieces of each of the groups in Fig. 5. In each case, the blanks are shown to the left. All that now remains for the completion of the pieces is to run them through blanking operations to trim off the surplus metal. While there is nothing especially difficult about doing this class of work after the tools and methods are designed, it requires presses which are extremely powerful, and above all, dies which will withstand the severe work they must do.

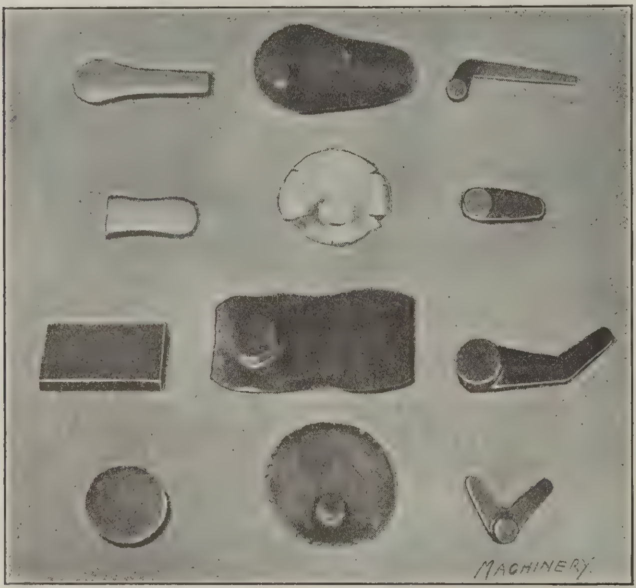

Fig. 5. Steps in making Cold-forgings

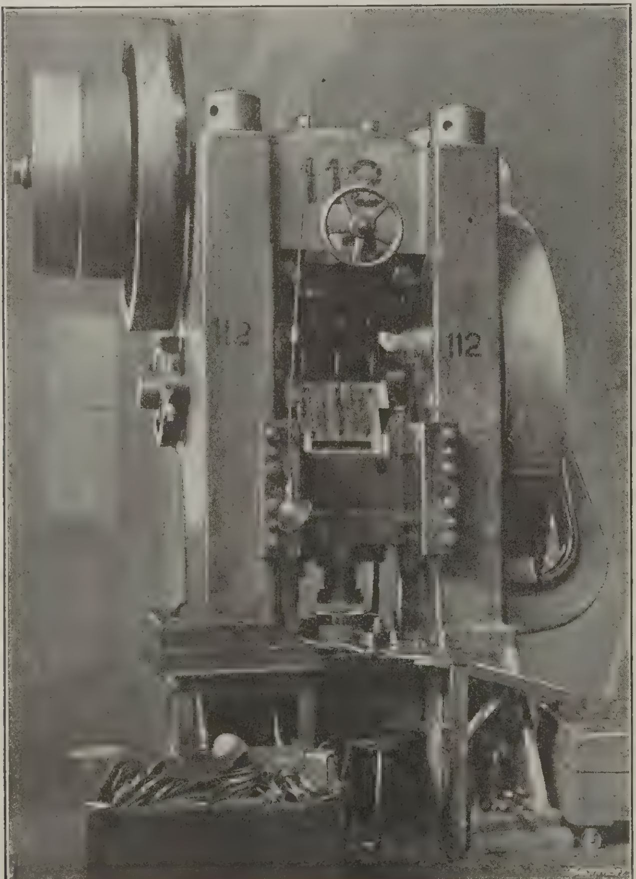

Fig. 6. Heavy Knuckle-joint Press used for Cold-forging

Fig. 7. Making a Difficult Stamping

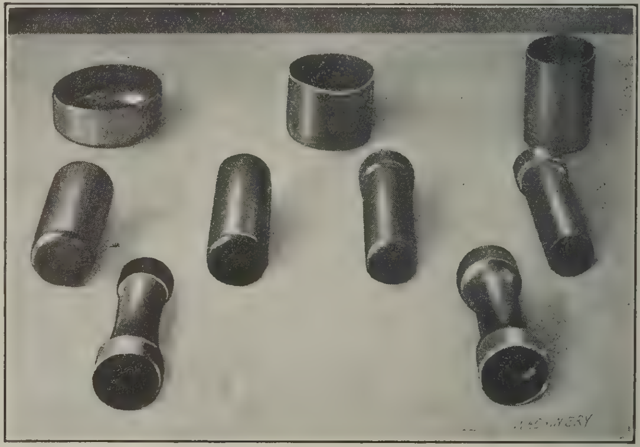

Fig. 8. An Unusual Stamping and its Evolution

Successive Steps in Forming Typical Stampings

Three sets of stampings showing the steps taken in making the respective pieces are shown in Figs. 7, 8 and 9. In Fig. 7, the piece shown is very difficult to produce, mainly on account of the small diameter of the small end. In producing this piece, the first step consists of cupping the blank, as shown at the extreme upper left-hand corner. From this blank, the stock is gradually worked toward the point to get enough metal into position to form the narrow thimble-shaped end, without enough strain being exerted upon the metal to tear it. The pierced end is, of course, the result of the final operation. The metal is kept a uniform thickness throughout.

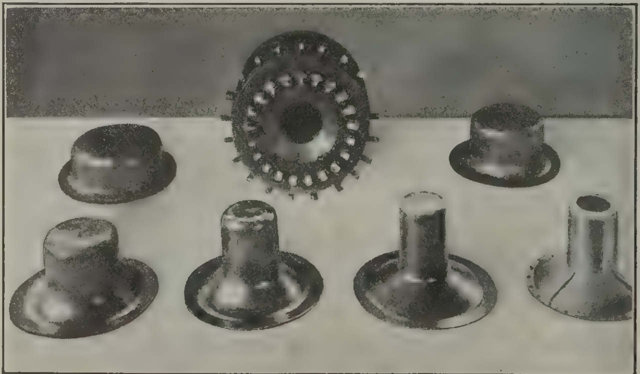

Fig. 9. Steps in Drawing a Flanged Cup and the Last Operation Punch

In Fig. 8, an unusual piece of work is shown in the making

of a special steel ferrule. The difficulty in producing this ferrule lies in the fact that it must be opened out from the small end after being drawn. It takes nine operations to complete this piece, the first operation consisting in drawing the shell in the usual way, leaving a shoulder at the mouth, and the final operations consists of punching out the bottom, expanding the small end and shaping the finished piece.

In Fig. 9, six steps in making the special stamping at the right-hand lower corner are shown, together with the piercing punch used in the final operation. Up to this final operation, the work consists of plain drawing, but the last operation embraces the cutting of the central hole, the formation of the ribs on the beveled section, and the piercing of the small cuts around the edge. It will be noticed that these cuts are not round holes, but are made by a combined shearing and forming operation effected by the special punch shown in the center of the illustration. The individual punches on this tool are held in position by set-screws so that they are easily renewable if broken.

Perforating Tools

Except by those directly connected with the manufacture of telephone mouth-pieces, it is not generally known that the best type of these pieces is made with a steel core be-

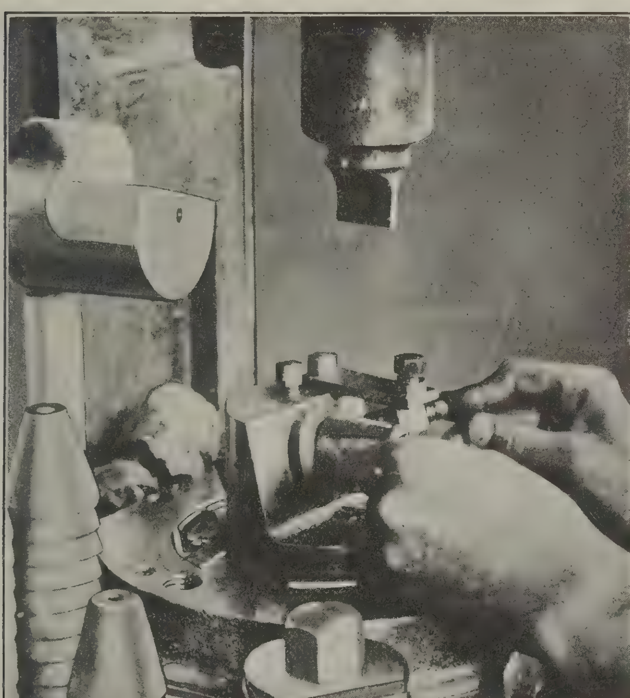

Fig. 10. A Simple Set of Perforating Tools

neath a hard rubber covering. It is, of course, apparent that the strength of such a mouth-piece exceeds the solid rubber article, and, moreover, more durable threads are secured when cut in the steel core than is the case when the threads are cut directly in the rubber. For the purpose of making the rubber adhere firmly to the steel core, it is necessary that perforations be made in the metal, through which the rubber can run. Two sets of tools for this operation are shown in Figs. 10 and 11. Fig. 10 shows the simpler set in which the die is mounted within the arbor, which is shown just behind the operator's left hand. This arbor is, in turn, supported by a base which is clamped to the press bed. The punch is shown directly over the arbor which, of course, holds the die. For indexing, a spring finger, the rear end of which is shown in contact with the operator's finger, is supported by a suitable bracket from the base of the fixture. Pressure upon the end of this finger causes the gaging end to extend, and the slot previously cut in the core is turned against the end of this finger while the next slot is being punched. This operation is repeated until all six of the slots have been perforated, when the finger is released and springs back out of the way. After the completed piece has been taken from the arbor, the six pieces of scrap drop through the arbor.

A second set of perforating tools is shown in Fig. 11. These tools are a little more complicated in design, but they are also more efficient and more interesting. They consist essentially of the bedplate upon which the base block of the fixture is mounted, supporting the work on the arbor, which may be seen at the center of the illustration. The punch is fitted with a spring stripper. The die, of course, is mounted in the arbor. Rotation of the work upon the arbor is secured by means of the automatic indexing mechanism, which is oper-

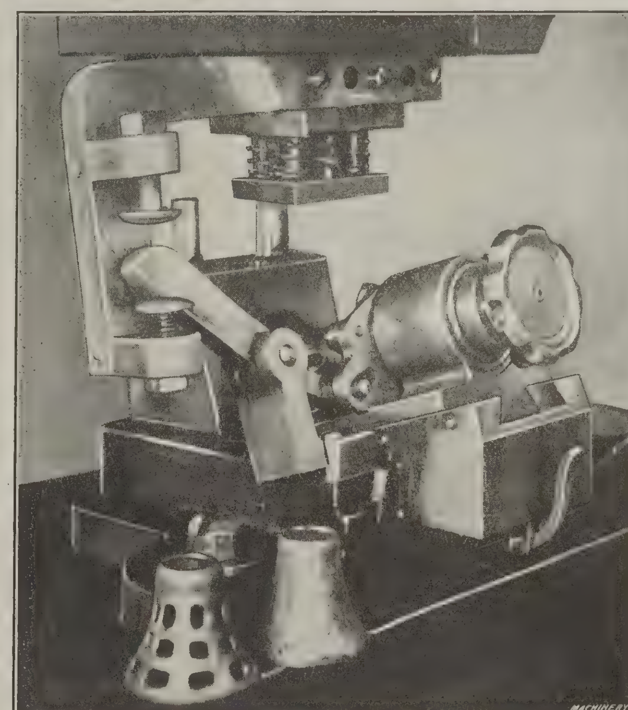

Fig. 11. Perforating Tools with Provision for automatically rotating the Work

ated through a bracket that extends downward from the ram of the press. This bracket is fitted with adjustable button head "pushers" which reciprocate the end of the lever, one end of which appears between the pushers. This lever communicates with the indexing plate by means of a pin at its opposite end. A handwheel operates a friction disk which acts against the end of the work. When the lever is depressed, the index plate turns the work by means of a ratchet, just 1/8 of a revolution; therefore, after the press has operated continuously for eight revolutions, a new piece is put on the arbor. The latch at the extreme lower right is used to facilitate the removal of the work.

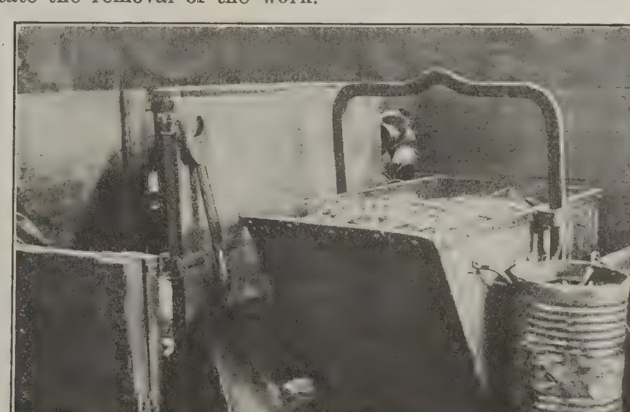

Fig. 12. Flexible Bins and Steel Buckets for Handling Stampings in Quantities

An important part of the work done by this concern is making high-grade rear axle housings, brake drums, hub flanges, hub caps, ball bearing cups and retainers, and other stamped parts for automobiles, motorcycles, bicycles, cream separators, textile and electrical machinery, and for many other purposes.

Production Methods

For handling steel stampings in large quantities many unusual methods are employed. In Fig. 12 may be seen a method

of bin construction which is used for handling heavy stampings in large lots. These bins consist of sections which may be fastened together, forming a semi-flexible arrangement that may be moved to any position on the floor and expanded or contracted at will, as there is no bottom. A method of transporting work about the factory, is by means of sheet steel buckets handled by an electric traveling crane. Punchings and stampings except those which are light and easily bent, are thus treated like so much building material, being shoveled into the bucket and dumped from it in the same manner. Small cans like that shown at the right, are common to all shops for holding small quantities of work.

Power is derived from a hydro-electric plant, situated on the Connecticut River, sixty miles away. This power is carried to the factory at a tension of 23,000 volts, at about half the cost of steam power if produced by coal at the plant. All the presses are driven by individual electric motors.

Credit is due Mr. F. C. Cutler, sales manager of the above company, for cooperation with the writer in preparing this article.

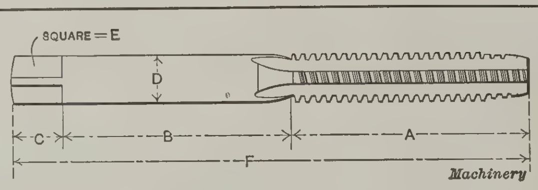
STOVE-BOLT TAPS

BY A

In the March, 1909, number of MACHINERY, an article accompanied with tables was published giving data for the making of stove-bolt taps. As is well known, there is no standard for this class of taps that has been accepted by all the different makers, and the diameters of taps made by different manufacturers vary to a great extent. The dimensions given in the upper part of the table below represent the practice of two of the more prominent tap manufacturers, the dimensions of whose stove-bolt taps agree with slight (and practically unimportant) differences. The dimensions for the pitch diameters have been obtained by measuring the taps with the ordinary type of screw thread micrometers for the

TABLE OF STOVE-BOLT TAPS



Nominal Size	Actual Outside Diameter	Pitch Diameter	Root Diameter	Flat in Bottom of Thread Corresp'ding to	Flat on Top of Thread, Inches	Number of Threads Per Inch
5/32	0.166	0.1500	0.134	20 U. S.	0.0110	28
3/16	0.197	0.1745	0.152	20 U. S.	0.0094	24
7/32	0.223	0.1965	0.170	18 U. S.	0.0079	22
1/4	0.257	0.2285	0.200	11 U. S.	0.0112	18
5/16	0.317	0.2855	0.254	10 U. S.	0.0067	18
3/8	0.354	0.3165	0.279	10 U. S.	0.0067	16

Nominal Size	A	B	C	D	E	F
5/32	7/8	1 5/32	7/32	0.166	1/8	2 1/4
3/16	15/16	1 3/16	1/4	0.197	9/64	2 3/8
7/32	15/16	1 1/4	1/4	0.223	11/64	2 7/16
1/4	1	1 7/32	9/32	0.257	3/16	2 1/2
5/16	1 1/8	1 5/16	5/16	0.317	15/64	2 3/4
3/8	1 1/4	1 5/16	3/8	0.354	9/32	2 15/16

standard number of threads per inch within the range of each micrometer. As the thread, however, is not a regular U. S. standard thread, but is provided with a wider flat at the bottom of the thread than that corresponding to the number of threads per inch in the taps, care had to be taken when measuring these angle diameters so that the spindle would not bear upon the flat in the bottom of the thread; in other words, the point of the spindle at *A*, in the accompanying illustration, had to be flattened sufficiently so as to clear the bottom of the threads.

It will be seen that some of the dimensions differ from those given in the March, 1909, number. It would, of course, be desirable to the trade if all the tap manufacturers could agree upon one standard, and it is believed that the table given herewith represents the practice to which probably the largest proportion of this class of taps conform. The thread has an angle of 60 degrees, with an arbitrary flat on the top, and a flat at the bottom corresponding to that of the standard U. S. thread for pitches coarser than the actual number of threads per inch in the tap. Hence the taps can be cut with regular U. S. standard thread tools selected for a coarser pitch than that of the thread to be cut. For example, when cutting the thread in a 3/16 inch stove-bolt tap, the lathe is

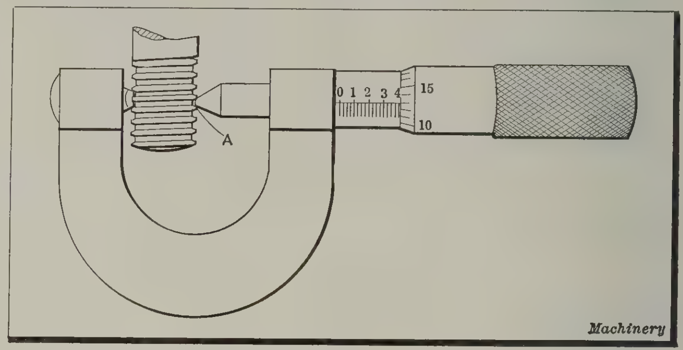


Illustration showing Modification of Point of Measuring Screw of Thread Micrometer for measuring Threads with Very Wide Flat at Bottom

geared to cut 24 threads per inch, but a threading tool for 20 U. S. standard threads per inch is used. It is of considerable advantage to settle upon a width at the bottom of the thread that corresponds to certain U. S. standard threads, because the expense and trouble connected with making special thread tools for these taps is thus avoided. As was mentioned in the previous article referred to, stove-bolt taps are made considerably larger in diameter than is the diameter of the screw, so that the nuts have a loose fit—a fit, in fact, that would not be tolerated for regular U. S. standard bolts and nuts. All taps of this kind have four flutes.

* * *

THERMO-ELECTRIC METHOD FOR TESTING THE STRENGTH OF MATERIALS

An interesting development in the testing of the strength of materials is that known as the thermo-electric method. It has been found that a bar of a given material, upon being subjected to a tensile stress, will absorb heat as long as the stress does not exceed the elastic limit of the material, but that beyond this limit heat will be generated by the friction of the particles sliding over each other. The observations are made by thermo-electric couples, the terminals of which are connected to a sensitive galvanometer. The elastic limit of the material is recognized by the reversal in the temperature curves, presuming, of course, that the temperature indication does not lag behind the stress to which the material is subjected. The extended experiments undertaken by Messrs. T. R. Lawson and J. A. Capp of Schenectady, N. Y., as recorded in a paper before the International Association for Testing Materials, at its congress, September, 1912, indicate, however, that the break in the thermo curve invariably occurs at a higher stress than the elastic limit, as shown by the extensometer.

* * *

FOURTH DIMENSION SPACE ANALYSIS

In a paper on the "fourth dimension" published in the *Polytechnic Engineer* for 1912, William J. Berry mentions a practical use for the mathematical analysis developed to prove the existence of four-dimensional space as follows: "The problem of motion in three-space is stated in terms of four variables—three for space and one for time. Now it is a well-known fact that the analogous problem in two-space may frequently be simplified by regarding it as a geometrical problem in three-space. The suggestion of a geometry of four dimensions to perform a like service for the problem of motion in three is inevitable. This is what makes four-dimension space analysis important, and is, in a large measure, the justification for its study."

THE MECHANICAL TESTING OF FILES*

THE DEMAND FOR STANDARD MECHANICAL TESTS AND TEST METHODS

BY GEORGE W. BURLEY†

The association of standard test specifications with the purchase of engineering materials and tools is a distinctly modern condition, though in certain outstanding cases, engineering materials have been purchased subject to their satisfactorily passing prescribed tests (more or less standard) for a considerable time. At present, however, it is an almost universal practice to demand standard tests on materials and tools where variations can exist in composition, design, construction, or manufacture. Practically nothing is left to chance, and any material or tool which does not excel, or at least equal the test standard, is rejected; if such material or tool represents a sample of any given quantity, the entire quantity is likewise condemned and rejected. The matter of a standard test is a most important one when viewed in connection with large contracts, as the acceptance of large quantities of materials or tools, which are not of the best quality obtainable at the purchasing price, is a source of loss that every progressive management seeks to eliminate. For this reason, the requirements of some commercial engineering departments are very stringent, though considering modern demands and needs, it cannot be said that they are anything but fair.

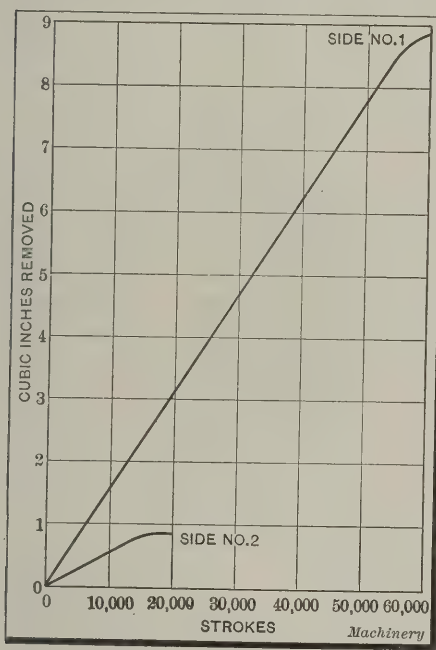

Fig. 1. Difference of 11 : 1 between Durability of the Two Sides of a File

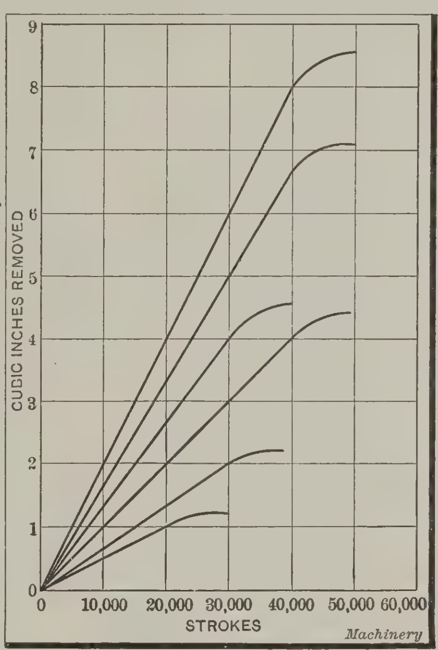

Fig. 2. Typical Curves obtained from File Testing Machine Recorder

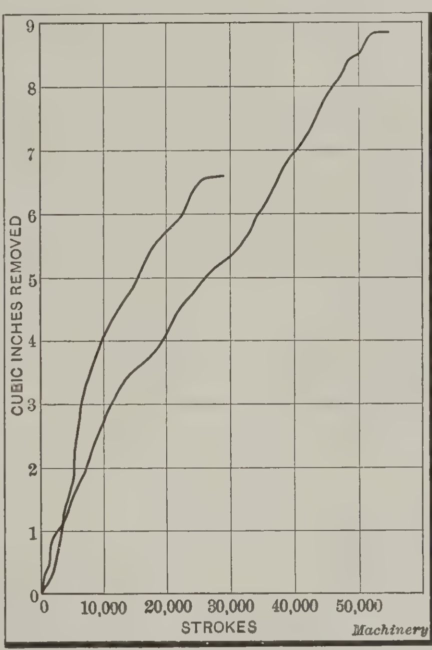

Fig. 3. Abnormal Curves showing no Dependence upon an Operating Law

Of the latest engineering materials and tools to come within the scope of standard commercial tests, one of the most important is the ordinary file, of which it is no exaggeration to say that tens of thousands are made, used, and worn out every year. Now in every file-manufacturing works, it has been the practice to test each file for sharpness by means of a "prover" before it is passed. A prover is nothing more nor less than a short piece of comparatively soft steel which is drawn over the face of the file by hand. If the prover drags as it is being drawn over the face of the file, the latter is passed; whilst if it slips too easily, it shows that the file is not cutting properly, and such files are rejected. This method of testing files, which in the hands of an experienced operator may produce fairly reliable results, is not entirely satisfactory because it depends too much upon the judgment of the workman for its results. Everyone knows that personal judgment is a variable quantity, and likely, therefore, to lead to variable results. In engineering works where files are used, the old-fashioned method of testing files—and one still in vogue in quite a large number of such establishments—consists of distributing files of the brands that are to be compared among a number of reliable workmen, with the order to try them on the materials ordinarily worked on in the shops and report as to the order of merit of the different brands. These reports express each man's judgment and form the basis of the decision of the purchasing department as to the brand to be finally selected when issuing orders for the files. This is not, however, a very reliable method of testing files, as it is a notorious fact that workmen can become so accustomed to the use of one brand of file, that even when called upon to choose between two or more brands, they will select the brand that they are used to—which they discover in some subtle manner—whether, in their honest opinion, that brand is better than the others or not. This is, of course, evidence of the conservatism of man.

Early History of Mechanical File Testing

Until the advent of the mechanical method of testing files embodied in the Herbert file-testing machine some five or six years ago, the above methods—each in its own sphere—were regarded as being the only two methods of testing files which were available—though a mechanical file tester has existed in a very crude form for something like twenty years. Mechanical file-testing can be adopted by both file manufacturers and file users—the former for the purpose of improving the cutting and wearing qualities of their products: the latter for the purpose of comparing files of different brands and also files of any one brand against the standard, in their effort to get the best that are available at the price.

The history of the mechanical testing of files, although so brief, is one in which conservatism and opposing interests have played a very large part. It is certain, however, that every manufacturer of high-grade files is now quite prepared to allow his products to be submitted to a mechanical test, provided the conditions of the test command his complete confidence. On the other hand, it is quite as certain that he will not willingly submit his products to a test in which he believes there is a considerable element of doubt as to the fairness and accuracy of the results. Consequently, it is of the utmost importance that the file test imposed should be one which commands the confidence of every one concerned—whether file manufacturer or file user. Care should be taken in applying the test to see that uniform conditions are maintained, and that the truth respecting any file is not masked by outside influences brought to bear on the machine or test. The Herbert file-testing machine was described in detail in the

* For further information on file making and file testing, see "Manufacturing The Vixen File," September, 1912, and other articles there referred to.

† Address: University of Sheffield, St. George's Square, Sheffield, England.

December, 1907, issue of MACHINERY. The results of tests made with this machine have been subjected to a tremendous amount of both favorable and adverse comment, on the part of file manufacturers and file users alike, though more especially the former. The reason why file manufacturers were and in many cases are still opposed to the use of the Herbert file-testing machine, for the purpose of determining the cutting qualities of their files and comparing them with a standard, has been because many of the results forthcoming were inexplicable and appeared to be contradictory. Thus, files which both manufacturers and users have regarded as being of the very best quality have given extremely poor results in the Herbert file-testing machine. In many cases, great differences in cutting power and durability are reported to have been discovered, by means of this machine, between the two sides of one and the same file. Similarly, files of the same grade and make have shown great variation, even when the utmost care has been taken in the process of manufacture to eliminate differences and to produce files similar in every respect. According to tests made on this machine, differences between the two sides of a file as great as 30:1 have been reported, while a difference of from 4:1 to 10:1 is by no means uncommon, even amongst the very best brands of files. Fig. 1 shows a difference of 11:1. Under ordinary circumstances of manufacture, it is not feasible to suppose that such huge differences can possibly exist, and it is these extraordinary results that have shaken the confidence of file manufacturers in the reliability of the results produced by file-testing machines.

There is, however, a real demand for a mechanical file test, notwithstanding the opposition of file manufacturers and others. The file-testing machine, in one form or another, has come to stay, and it will sooner or later be recognized as a necessity in the domain of engineering testing, where it will be used in connection with all large contracts for files. With this idea in mind, the subject of mechanical file-testing has been investigated during the past three or four years by Dr. W. Ripper and the writer in the laboratories of the Applied Science Department of the University of Sheffield, where a Herbert file-testing machine has been installed and thoroughly examined, together with the results which have been obtained from it. The method of procedure followed with this machine is briefly given: The file to be tested is held rigidly between two headstocks, which are carried on a reciprocating table. The test bar is supported on grooved rollers, in a horizontal position normal to the direction of motion of the table and file, and is pressed against the face of the file by means of a rope and weight. The movement of the file over the end of the bar causes a portion of the metal to be removed at each cutting stroke, the amount depending upon the composition of the material of the bar and the cutting power of the file under test. The file cuts on the forward stroke only. At the end of this stroke, the bar is drawn a short distance from the file by means of a clutch mechanism. This condition is maintained throughout the backward stroke, at the end of which the bar is released and allowed to come again into contact with the face of the file. The pressure of contact is 30 pounds per square inch, since the cross-sectional area of the bar is one square inch and the weight is one of 30 pounds. This pressure is maintained throughout the cutting stroke, the length of which can be varied to suit the conditions. To prevent chattering and jarring, and undue deflection of the file, heavy weights are supported on a rest which is carried by one of the reciprocating headstocks, these weights pressing on the back of the file. A recording apparatus is attached to the machine, the number of cutting strokes made and the number of cubic inches of the bar filed away, up to any time after the beginning of the test, being instantly obtainable from the curve which is automatically produced.

Cause of Errors in Mechanical File Tests

The early experiences of Dr. Ripper and the writer led them to believe that this machine possessed one or two defects, to determine the exact character of which, repeated and extended experiments were made. In the first series of experiments, only the best files of well-known makers were tested, the object being to eliminate, as far as possible, all outside influences upon the results of the tests. The results of the tests were quite normal in some cases, but in the majority of the cases, extraordinary and unaccountable differences of effectiveness or cutting power appeared to exist, both between files of the same batch and between the two sides of the same file. On examining the diagrams obtained from the machine during the tests, and also diagrams obtained from other machines, it was impossible to fail to notice at least two points in regard to their unusual character. The first point to be observed was the peculiar shape of each curve, this giving no evidence of the existence of an operating law. Two general forms of diagram or curve were discovered. The first, examples of which are shown in Fig. 2, is the more usual; the lower section is practically a straight inclined line, with a very slight curve at its upper end turning it into the horizontal. The other form is a zigzag line, examples of which are represented in Fig. 3; these diagrams show no signs of regularity and appear to contradict every mechanical law likely to operate in such a case as this. The second point to be observed was the great apparent difference in cutting capacities, which were found by means of this machine to exist between files belonging to the same batch, and between the two sides of the same file. In regard to the first point, we shall have to consider the nature of the file, and

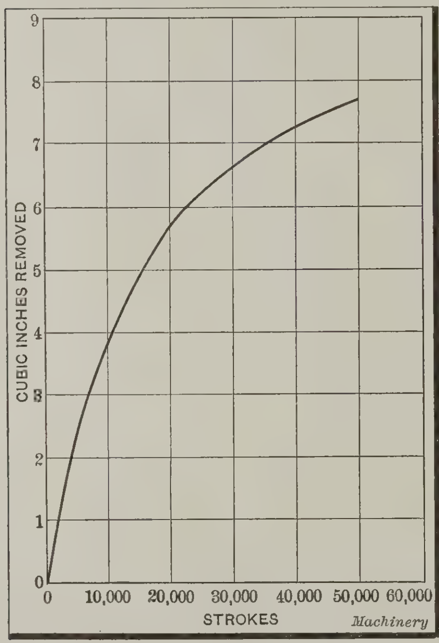

Fig. 4. Diagram showing Gradual Blunting of Files

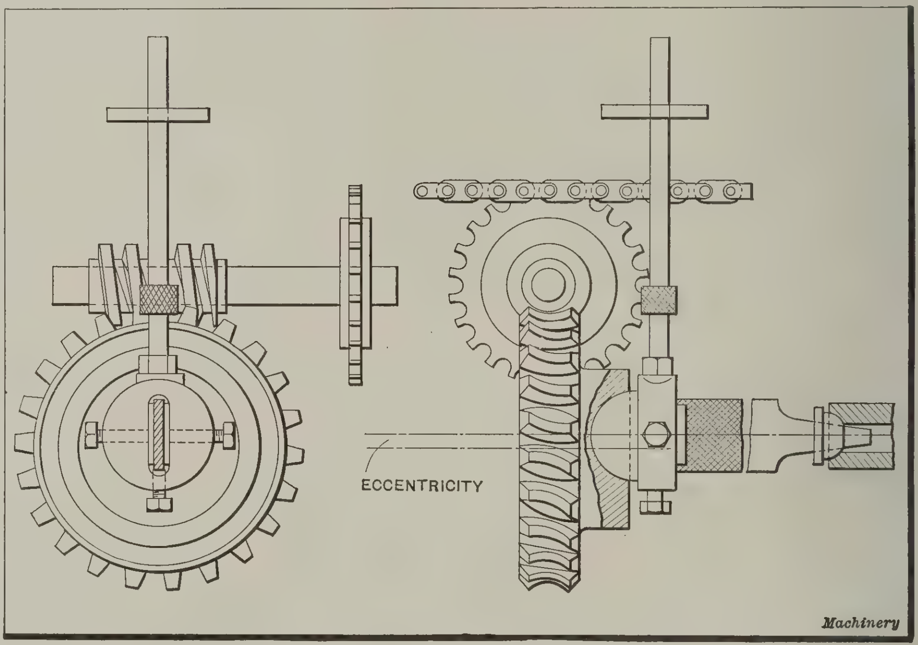

Fig. 5. Mechanism for changing Relative Position of File and Work

the action of the machine upon it, to discover whether such curves are reasonable or not. In some quarters, the file is regarded as a cutting tool which works on the wedge principle, though in essence, its action is more like that of a scraper. Its teeth are small projections, which in the case of a new file, should have sharp edges. These teeth are capable of being pressed more or less into the end of the test bar under the influence of the weight of 30 pounds. The initial cutting capacities of these teeth depend almost entirely —other things being equal—upon their sharpness, and the depth that they are caused to penetrate in the end of the bar. From the very beginning of the test, the influence of the bar upon the teeth of the file is in the direction of blunting them, so that as the test proceeds, the teeth become blunter and blunter. Accompanying this condition, there is a reduction in the depth of penetration of the teeth in the bar, although the pressure upon the file per square inch of bar surface remains constant. This reduction is due to the increase in the area of the flats on the teeth.

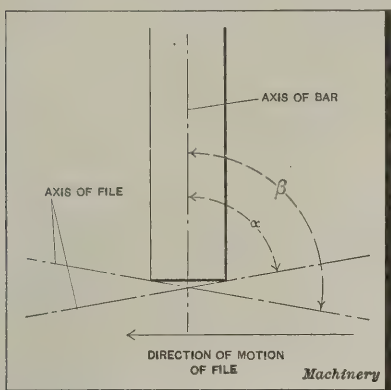

Fig. 6. Diagram showing Influence of Position of File on its Ability to cut

From the foregoing, it would seem to be fairly obvious that as the test proceeds, the rate of cutting should show signs of falling off, this being indicated in the diagram Fig. 4 by a curve, having a tangential tendency towards the horizontal which increases as the test proceeds. Under these circumstances, it is almost impossible to conceive the teeth of such a tool as the file retaining their original sharpness until the end of the test is nearly reached, and then suddenly ceasing to cut without any intermediate condition of cumulative bluntness. The irregular curves appear to be entirely beyond the ingenuity of man to explain in any reasonable and acceptable manner. In the course of the experiments already referred to, it was discovered that the cutting power of the side of a file, as indicated on the chart of the machine, was affected in no inconsiderable manner by the position of the file between the headstock, and by the relation of the axis of the file to the axis of the test bar. Thus, in practically every case which came under the notice of the writer in making these tests, the file would not cut at all if it was presented to the bar so that the angle between the axes of the file and the test bar on the leading side of the latter, as indicated by β in Fig. 6, was greater than 90 degrees; if the angle was reduced so as to be less than 90 degrees, as shown at a in Fig. 6, it would generally commence to cut. It was also discovered that the exact value of the angle between the two axes determined the rate of cutting, to a certain extent, the angle corresponding to the best position of cutting for one file not, necessarily, being the same as the corresponding angle for another file, although in most of the cases the differences were very slight. These differences, however, were sufficient to affect the results materially. It was found that the limiting angular positions of the file, for maximum cutting powers, were those in which the point end of the file axis was 1/32 inch and 5/32 inch, respectively, beyond the heel end, these measurements being made in a direction parallel to the axis of the bar and normal to the direction of motion of the file.

From a consideration of this subject, it will be seen at once that since there is such a wide diversity, it is impossible to select the best cutting position of the file in any particular case; it can only be accomplished by sheer accident. This partly accounts for the wide apparent differences in the cutting capabilities of approximately equal files. As the result of a further examination of the machine, it appeared that the mechanical action differed materially from the action of hand filing. The machine, as originally designed, holds the file so rigidly that it moves across the end of the test bar in an absolutely constant and unchanging path, while in the case of hand filing, the path of the file is changed more or less at every stroke. Therefore, the conditions of a mechanical test made on this machine differ from those which obtain when the file is used in actual practice, the result of maintaining a constant direction of motion being the formation of grooves in the end of the bar, the glazing of the face of the file, and the refusal of the latter to cut, even though it may not be worn out. To eliminate these defects in the action of the machine, Dr. Ripper and the writer designed and constructed a mechanism which, when added to the machine, removes the condition of constancy in the direction of motion of the file and its attendant influence upon the results, and causes the file to pass through a number of different angular positions with respect to the test bar, between the two extreme best cutting positions for all files as referred to above. At the same time, files of the same kind and size are treated in exactly the same way, so that the conditions of the test are maintained constant. By this means, the grooving of the end of the test bar by the teeth of the file is prevented, and each file is caused to give an average result for all the positions occupied. There are forty-eight of these positions in a complete cycle; at least one of these, and in the majority of cases two, is the best cutting position. The result obtained by the improved machine is the average cutting power of the file, and not its

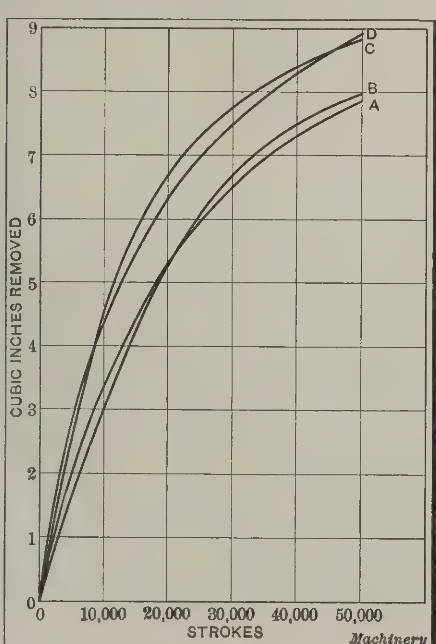

Fig. 7. Curves for Sides of Two Files of the Same Make

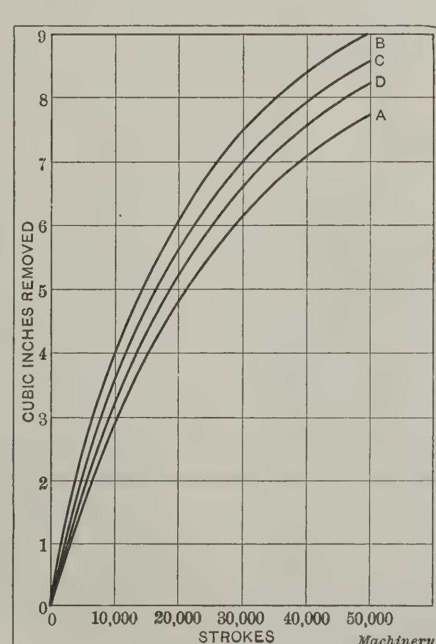

Fig. 8. Curves for Sides of Two Files that are all of the Same General Order

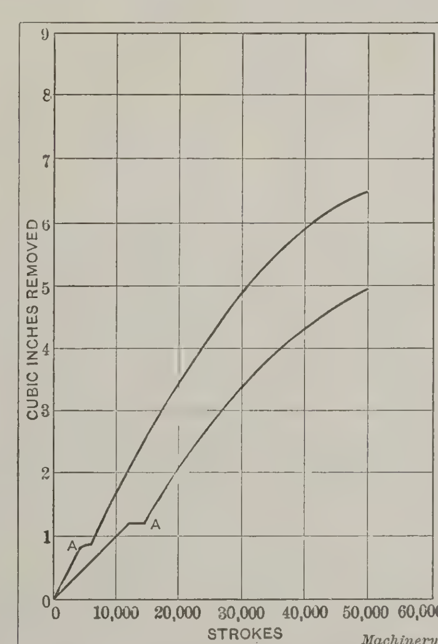

Fig. 9. Effect of changing Position on Durability of File

best or worst cutting power. Thus the results of all tests when this mechanism is used—provided, of course, that the other conditions of the test are maintained constant—are comparable with each other.

Mechanism of the Improved File Testing Machine

The mechanism by means of which this movement of the file is accomplished, is shown in Fig. 5. It consists of two ball-and-socket connections between the two ends of the file and the headstocks. The socket at the heel and tang end of the file is fixed in its headstock, while the other socket is arranged so that its center has a slight rotary movement, which is transmitted through the ball to the point end of the file. In this circular path, there are forty-eight different positions which are equally spaced, and these positions are occupied by the point end of the file during successive cutting strokes. The radius of the circular movement at this end of the file is 1/16 inch. The rotating socket is formed in the boss of a worm-wheel, which is mounted on the headstock, but set eccentric with it, as shown, the eccentricity being 1/16 inch. The worm-wheel is driven by a worm that is mounted on a plain shaft, the outer end of which carries a free sprocket wheel. The chain which meshes with this wheel is fastened to two fixed points on the frame of the machine. By this means, the sprocket wheel, having the same reciprocating motion as the table and file, is caused to rotate through its engagement with the fixed chain. This rotation is transmitted to the worm-wheel and ball-socket during the return or non-cutting stroke. During the cutting stroke, the sprocket wheel is traveling in the other direction and rotates quite freely on its hub, which is keyed to the worm-shaft; during this stroke the worm-wheel and socket are stationary, and the position of the file is not changed. Consequently, a change in the position of the file is made for each double stroke, and during each cutting stroke the file is presented to the end of the bar in a slightly different position from that occupied by it during the preceding strokes. There are forty-eight different positions in a complete cycle and the time required to complete a cycle is just under one minute, since the machine makes fifty double strokes per minute in its original form.

The point of the file is secured in the ball-holder by means of four set-screws and two small steel wedges. One of these set-screws is extended and attached to a bent arm, which rests on the reciprocating table and travels with it. This prevents the file from rotating on its own axis, as it would have a tendency to do if secured too firmly between the two headstocks. The wedges were found necessary to bring the point of the file exactly in the middle of the slot in the face of the ball. The tang of the file is inserted in a small ball holder which rests in the cupped end of adjusting screw of the headstock. This screw is longer than the one which is usually supplied with the machine, an additional nut being used on the other side of the headstock boss to get delicate adjustment of the file between the two headstocks. For files of different lengths, eccentricities of different amounts may be used, but this is hardly necessary—though some regard it so—because, in practice, it is not generally required to compare files of different lengths, so much as different files of the same length and grade. If desired, the pitch of the worm and wheel could be made different from that selected in connection with the original design, so as to obtain a cycle of positions of greater or less duration than one minute. It should be observed that the face of the file presented to the bar is not, except in two positions at the most, vertical; these two are the extreme inner and outer positions. In all other positions, the face of the file is more or less inclined to the vertical, the inclination being in one direction for half of the positions and in the other direction for the other half.

Conclusion Drawn from Carefully Conducted Mechanical Tests

A very large number of tests have been made with this apparatus on all makes and sizes of files. The majority of the results have shown that the defects found in files by the ordinary method of testing do not exist, while in no case do they exist to anything like the same extent that the ordinary test results suggest. The curves obtained by means of this apparatus are of the general character of the representative standard curve shown in Fig. 4. They show the gradual reduction in the cutting capabilities of files during the progress of the test, which can reasonably be expected. Figs. 7 and 8 show representative curves obtained by this method. The curves *A* and *B*, in each figure, represent the two sides of one file, the curves *C* and *D* representing those of another file of the same make. The two figures represent two different makes. It will be observed in Fig. 7 that there is very little difference between the two sides of each file, in a test whose length is 50,000 strokes, although it will be seen that in neither case are the two curves of exactly the same order, since they intersect, the first in one place, and the second in two. In Fig. 8, all the curves are of somewhat the same order there being no intersection of the pairs. There is, however, a greater difference between curves *A* and *B* than between curves *C* and *D*, based on a test of 50,000 strokes. On the other hand, the difference between the two files represented by Fig. 7 is greater than that represented in Fig. 8.

The results of tests extending over a very long period indicate that such differences as 30 to 1, or 10 to 1, or even 4 to 1 do not exist. The ratios commonly found range from 1 to 1 to 1.20 to 1. Other experiments with this method of testing have produced results which show conclusively that, in the case of a new file, every one of the forty-eight positions of the file has a corresponding cutting power. This cutting power is usually different for each position, so that the test invariably gives an average result, which is a much fairer result than any other. A number of experiments have also been made to determine the effect of the application of this varying position principle in cases where, according to the ordinary test, files were worn out—that is, had ceased to cut in the machine. The result was conclusive in every case; at the same time, it was astounding. Fig. 9 represents the results graphically. In the case of each curve, the point *A* is the break-down point, where, in the ordinary test, the file ceases to cut. By putting the position-changing apparatus into action, each side was caused to start cutting, and to continue cutting so that the file did not actually give out at the end of 50,000 strokes. From the results of many tests, of which the above are samples, it is felt that this apparatus supplies a much needed element to the test, and enables both file manufacturers and users to repose greater confidence in the results of the tests than has hitherto been the case.

In conclusion, and as an apposite addendum to the above, it may be pointed out that the exact chemical composition and physical properties of the test bar have a considerable influence upon the results of the tests. As there does not appear to be a test bar which is universally recognized and employed as *the* standard, it cannot be said that the conditions of file-testing are in a very healthy state. To demonstrate the fact that the influence of the physical properties of the test bar is no inconsiderable factor in the problem of file-testing, some tests were made with two similar files from the same batch on two test bars, one having a Brinell hardness numeral of 241 and the other of 186. Each file made 20,000 strokes, in which only 2.75 cubic inches of the hard bar was removed by one as against 6.25 cubic inches of the other. This is conclusive evidence that for a *standard* test there should be a *standard* test bar.

* * *

Near the old sun temple at Baalbec, in Syria, there is an enormous cut stone, probably the largest cut and finished piece of stone in the world. It is about 72 feet long, 13 feet wide, and 16.5 feet high. It is believed that the stone was intended for the sun temple which is now in ruins. There are still in the heavy walls of this temple stones of similar dimensions. Several that have been measured are about 66 feet long. These stones are placed in the wall at a height of nearly 20 feet above the ground. No indication of mortar can be detected, but the stones are so carefully cut and polished on the surface that it is only with difficulty that the joints can be detected. In fact they join so closely that a thin knife edge will not enter between them. How these blocks of stone could be lifted to such a height, and how buildings of this type could be erected, is one of the secrets of a past age of engineering.

SOME GOOD RESULTS OBTAINED BY THE BONUS PLAN

BY W. L. MYLES*

Much has been said and written regarding the advantages and disadvantages to both employer and employe of the bonus or premium plan of pay. Men who have given this plan a fair trial have attributed credit to it for obtaining lower manufacturing costs and higher factory efficiency for the employer, and higher wages for the employe. On the other hand, the bonus plan has been subjected to some hard criticism, principally by those who have never seen it in operation, or by those who are entirely unacquainted with its fundamental principles and ability to produce results.

Speaking from an experience of five years with the bonus plan, the writer believes that it is one of the best systems,

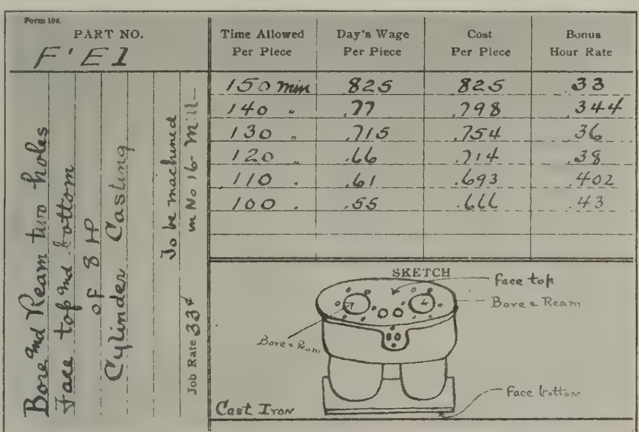

Fig. 1. Rate Card, showing Time allowed per Piece and Rate paid per Hour—4 by 6 inches

if not the best system, now in vogue, for justly compensating the workman for the extra effort he puts forth. This plan is also instrumental in obtaining those results so earnestly sought by the manufacturer or employer, *viz:* lower costs and greater efficiency of production. One of the advantages of the bonus plan is that it justly rewards the mechanic for extra effort; it creates a spirit of cooperation which would not exist under other conditions, and lifts the mechanic and the shop to a higher plane of efficiency. This will amply repay

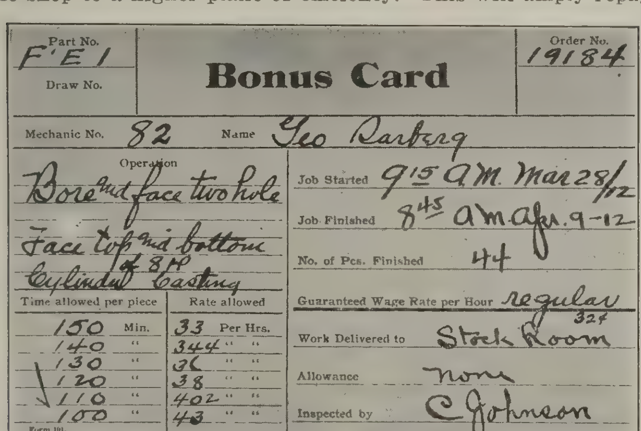

Fig. 3. Bonus Card, showing Time allowed per Piece, Rate per Hour, and what Operations to perform—4 by 6 inches

the employer for its installation. Under the bonus plan, the mechanic realizes that the management is interested in him, and he knows that if he gives an honest day's work he will receive an honest day's pay. The amount of that day's pay is entirely in his own hands, for the more work he turns out in a given time, the more pay he receives. This system teaches him that the ability to turn out more work in a day does not require a greater amount of physical exertion, but less, for by following the methods outlined on his instruction card, he uses a little more brain energy and less physical energy to produce the same amount of work. Some of the critics of this system have claimed that it is unfair to the mechanic, as it makes a mechanical tool out of him, rendering him an object for the scrap pile in a short time. It has been proved, however, to the satisfaction of these critics, that this is entirely wrong. The tendency of this system is to awaken the mechanic out of that dreamy mechanical state in which many of our workmen are today, into new, energetic men; for, in order to earn their bonuses, they realize that they have to use their brains and hands at the same time, thereby avoiding many mistakes and accidents. The reward of extra compensation is sufficient to repay the mechanic for his extra effort which, in a great majority of cases, is but a matter of giving a little more thought and attention to his work, reducing instead of increasing the physical effort formerly employed. It is a known fact that 90 per cent of the workmen of this country are accomplishing less than 60 per cent of what they might do without physical injury or over-exertion.

Under the bonus system, in one shop the writer has in

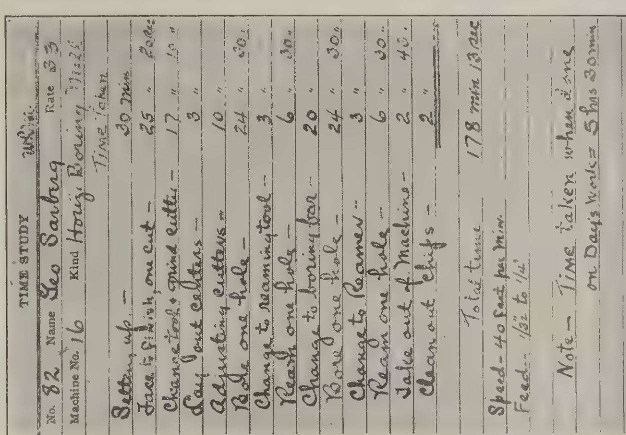

Fig. 2. Detailed Record of Results of a Typical Time Study, on Back of Rate Card

mind, the men are doing 40 per cent more work with about 25 per cent less physical effort. Why is this? Partly because the management has standardized the tools and equipment, and provided the mechanics with instruction cards which show exactly how the work should be done, thus eliminating many unnecessary moves. But it is mainly because the bonus offered is large enough to supply the needed incentive. Many have asked the question, "Do the majority of those working under the bonus plan earn bonuses, or is it only those who

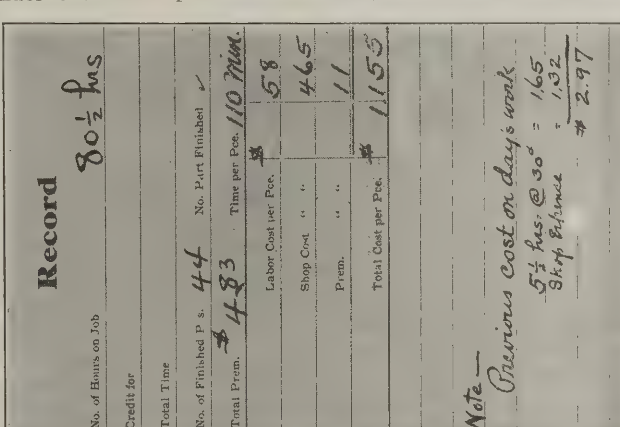

Fig. 4. Cost Record of the Operation, on Back of Card, filed for Future Reference

are most rapid and experienced in their particular line?" The writer can readily answer this question by referring to a chart kept by him, which shows the percentage of each class of workmen that earned bonuses. For the first three months of the present year, over 75 per cent of the men earned bonuses which gave them an average increase of 8.5 cents per hour, or about 30 per cent higher wages. Through the opportunities offered by this system for men to show their ability in mechanical lines, laborers and helpers have turned out to be good mechanics, and mechanics have become functional foremen, thereby increasing their earning power and adding materially to the efficiency of the plant.

The following is a general outline of the procedure followed in making time studies, setting rates, and issuing bonus cards, together with forms used by one of the leading manufacturing

* Address: 172 Whiton St., Jersey City, N. J.

concerns of New Jersey, which has operated this plan successfully for some years. In order to correctly set a time and price on a piece of work, it is necessary to know each operation and move needed to complete the work in the shortest and best way. When a job is to be put on bonus, a detailed time study is made; the machine best suited for the operation is next decided upon, correct tools are supplied, and belts and equipment are brought up to proper speed. Each operation is timed separately with a stop watch; then an overall time is taken to verify it, a fair amount of time being allowed for grinding tools, etc. Fig. 1 shows a form of rate card, giving the time allowed per piece and the rate paid per hour. On the back of the rate card, there is a record of the detailed time study. It will be seen that decreasing the time per piece increases the rate paid per hour. After the time study is complete, a bonus card is issued to the mechanic to start with the work. This form includes the time allowed per piece and the rate paid per hour, also what operations to perform, the time of starting and finishing job, the part number, etc. A cost record of the operation is kept on the back of the bonus card, which is filed away for future reference.

The men are guaranteed their regular day's pay, whether they make the pieces in the allotted time or not. When the job is finished, the time of finishing is stamped on the card and the number of pieces is recorded; the card is then taken to the foreman, who verifies the number of pieces and inspects the work, if no regular inspector is employed. The finishing time of the last job is always the starting time of the next job, except where special time is allowed for repairs or some other necessary work, other than the general up-keep of the machine. This eliminates a large amount of time that was formerly lost between jobs, when done under the old day-work system. The foreman's task of answering a lot of unnecessary questions, and standing over a man in order to keep him at work is reduced 50 per cent, as the instruction card states plainly what is to be done and all other information that is required on the job. Needless to say, the men working under the bonus system require no watching; all their time and attention is required for their work, if they wish to earn their bonuses.

Some of the results obtained by working men on the bonus plan of pay can be summed up as follows: Higher wages and greater efficiency for the mechanic. A reduction of the number of accidents, for many an accident is caused by inattention to work. A method of showing the foremen who are the non-producers or "deadheads" in their departments. A reduction of the "overhead" expenses of the plant. Simplification of the method of keeping costs and the production of far more accurate cost records. A reduction in the cost of manufacturing, and a marked increase in output. In general, the bonus plan benefits all parties concerned and compensates the mechanic as no other system can. For the greater effort put forth by both employer and employe, a material increase in efficiency is seen throughout the whole plant, and in addition, there is that spirit of cooperation between both parties that is so essential to a successful business.

IMPROVED TYPE OF COUPLING BOLTS

A recent number of *Page's Weekly* describes a practical type of coupling bolt which was designed to do away with the difficulty experienced in extracting the bolts when it is necessary to disconnect a shaft. The advantage of such a design will be apparent to any sea-going engineer who has had experience with broken shafts at sea. According to the writer the corrosive action of salt water upon ordinary steel is such that he has known it to take a week to get out twenty-four three-inch bolts, while the same work can be done in an hour where the improved type is in use. Figs. 2 and 3 show cross-section views of coupling flanges connected with the old style bolts. These two types are identical, with the exception that a head is provided on the bolt shown in Fig. 2, while the type shown in Fig. 3 depends entirely upon the taper for holding it in the flange. Both of these bolts are made of steel. Fig. 1 shows the improved type of bolt previously referred to. In this case it will be seen that the regular nut is provided at one end for tightening the bolt, while a similar nut is provided at the opposite end for drawing the bolt when it becomes necessary to disconnect the shaft. The nut *B* used to tighten the bolt, is best made of "Delta" metal or some similar tenacious metal of a non-corrosive nature, and washer *C* is of similar material. The nut *D* used for starting the bolt is made of non-corrosive "Sceptre" bronze with a washer of similar material. Before putting the bolt in place, it is thoroughly coated with a mixture of flake graphite and castor oil which further protects from corrosion.

"EXPLOSION-PROOF" ELECTRIC MOTORS

The United States Bureau of Mines, Washington, D. C., has issued a bulletin (No. 46) regarding the results of an investigation of explosion-proof electric motors. The term "explosion-proof" as applied to an electric motor refers to a motor enclosed by a casing so constructed that an explosion of a mixture of mine gas (methane) and air within the casing, will not ignite a mixture of the same gas surrounding the motor. There are two classes of motors so constructed: First a class totally enclosed and built strong enough to withstand internal explosion pressures and so designed that the efficiency of all the enclosing covers can be satisfactorily maintained; second, a class provided with relief openings or valves designed to cool any products of combustion discharged through the valves. The results of tests are given in detail in the bulletin. These tests are of interest to other than mine operators, as explosion-proof motors are desirable in situations such as flour mills and other plants in which explosive gases incident to the processes of manufacturing sometimes collect.

EVOLUTION OF A SKYSCRAPER

In a paper entitled the "Evolution of a Skyscraper," read before the American Society of Swedish Engineers, 271 Hicks St., Brooklyn, N. Y., November 2, 1912, Mr. N. L. Malmros made reference to some antiquated provisions that are still part of the building laws of New York City, and which indicate how difficult it is for the law-making bodies to keep pace with the advances in science and engineering. The building law of New York City contains provisions which were unsuitable and unnecessary even twenty-five years ago. One of these provisions is that relating to wall thicknesses, which works a hardship and an actual disadvantage from all points of view in the erection of high buildings. The modern steel skeleton structure does not depend on the masonry walls for support; instead the steel frame supports and holds the masonry in position. The function of the walls is principally to afford protection against the weather and fire, and as the walls are carried entirely by the steel framing at every story, their thickness need be no greater at the bottom than at the top. Nevertheless, the building laws at present in force in New York City require as great a thickness of wall in the lower stories as though they actually carried the weight of the building. As an example, it may be mentioned that a building one thousand feet high would have walls six feet thick at the ground floor. The unpierced walls along the lot lines facing adjoining buildings would have to be solidly made of this thickness for several stories up. This involves not only a waste of rentable space but places an enormous dead load on the steel structure and on the foundations—a load which detracts rather than adds to the strength and safety of the building construction. Strong efforts have been made within the past two years to frame a suitable and sane building code, but these attempts have all failed by reason of the conflicting and warring interests within the building material industries.

Mr. Malmros mentioned that he expected to see still higher buildings in New York City than the Woolworth building now nearing completion, which is about 750 feet high. He mentioned that he had been connected with the design of a proposed building 1100 feet high, of about eighty stories, which careful calculations showed, would have proved a good investment. The limiting factor in high buildings is the transportation facilities within them, and the large space taken up for elevators, halls and stairways, which require a proportionately larger space the higher the building is made. As far as the steel construction is concerned, there is no reason why a building 2000 feet high could not be erected.

Reference was made to the Singer Building, of which Mr. Malmros, acting in a consulting capacity with Ernest Flagg, was the architect. As an interesting illustration of the great amount of work connected with the building of a skyscraper of this type, it may be mentioned that the specifications covered more than eight hundred typewritten pages, and that the number of trades employed in the building of this structure, for which separate contracts were let, numbered more than seventy-five. About 1500 drawings were made in the architect's office for this building, besides all the shop and construction drawings made by the various contractors, which were also checked and corrected in the architect's office. A peculiarity of the very high building is that on account of the enormous wind pressure to which it is exposed, and its proportionately small base, it must not merely be placed upon its foundation but must be actually anchored down very securely.

* * *

A pressure of from four to thirty-five pounds per square inch of surface on work being ground on a disk wheel is recommended by the Gardner Machine Co., which has experimented extensively in determining the proper pressures for grinding. A less pressure than four pounds per square inch results in polishing and burnishing the work. For this reason it is necessary, when grinding light pieces on a horizontal disk wheel, to load them with weights when the weight of the piece does not impose a pressure of more than four pounds per square inch.

TURNING ELLIPSES IN THE LATHE

BY GEORGE E. POPE*

The writer believes that the following method of turning an ellipse in a lathe has not found wide application for two reasons: it will be evident from the description that it has a rather limited scope, and the principle has probably never occurred to a great many men. The possibility of applying this method is controlled by several considerations, *i. e.*, the length of the ellipse to be turned must be comparatively short, it must be on the end of a shaft, pin, or similar part, and the ratio of the major to the minor axis must not be too great. These conditions are all met with in the case of the emergency brake cam shown in Fig. 1. The design of this cam was changed from one whose section is shown in Fig. 2; this illustration also shows the method of milling with a formed cutter, the cam being milled on one side and then turned over to have the other side formed.

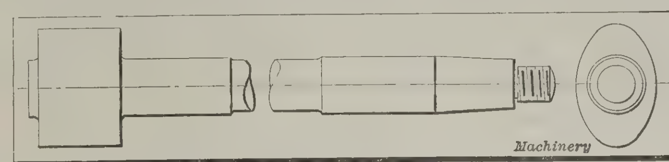

Fig. 1. Elliptical Emergency Brake Cam turned in a Lathe

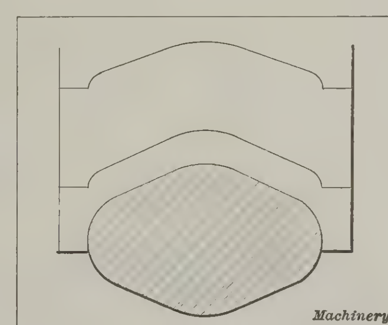

Fig. 2. Former Type of Cam produced by Formed Cutter

In Figs. 3 and 4 are shown a plan view, a partial side view, and sections of the device for turning this cam in a lathe, after changing its design to an elliptical section. Referring to Fig. 3, the device will be seen to consist in part of a square steel block *A*, that is tongued into and bolted to the faceplate and carries the fly-cutter *C*. The remainder of the device consists of the cast-iron block *B* which is tongued into and bolted to the upper surface of the compound rest of the lathe, as shown plainly in Fig. 4. A bushing *D* carries the cylindrical end of the work which has already been turned to size. This bushing is split through one side and is closed in firmly on the work by means of the bushing locks *L*; it is prevented from rotating by the pilot on set-screws *S*. This bushing can easily be replaced by others of different sizes, thus making the fixture adaptable for various sizes of work.

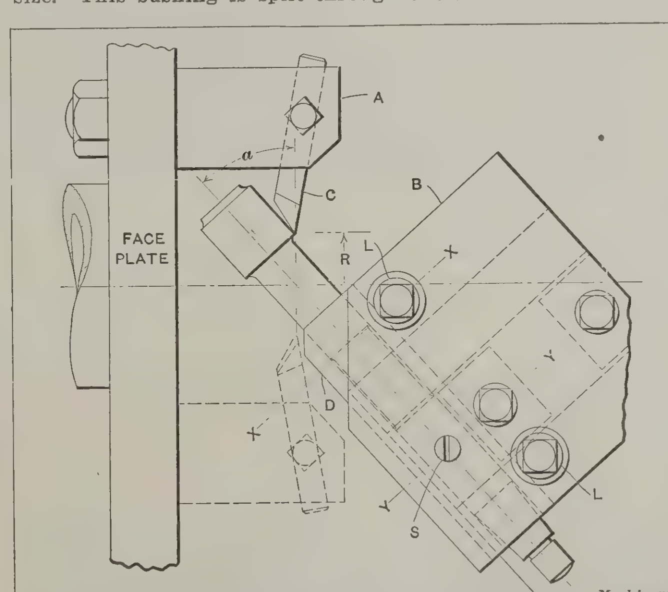

Fig. 3. Fixture for turning an Ellipse in a Lathe

It will be readily seen from Fig. 3 that in order for the elliptical section to be concentric with the shank, the axis

*Address: 832 State St. Bridgeport, Conn.

must pass exactly through the center of the circle generated by the point of the fly-cutter C. This is accomplished by taking care that the height H in Fig. 4, from the surface of the compound rest to the center of the split bushing, corresponds closely to the height from the surface of the compound rest to the center of the lathe spindle, and by adjusting the longitudinal position of the carriage, taking light cuts over the cam and measuring for concentricity. A positive stop can then be clamped on the ways of the lathe to engage the forward end of the carriage, as the carriage must be moved away from the faceplate in order to remove the finished part.

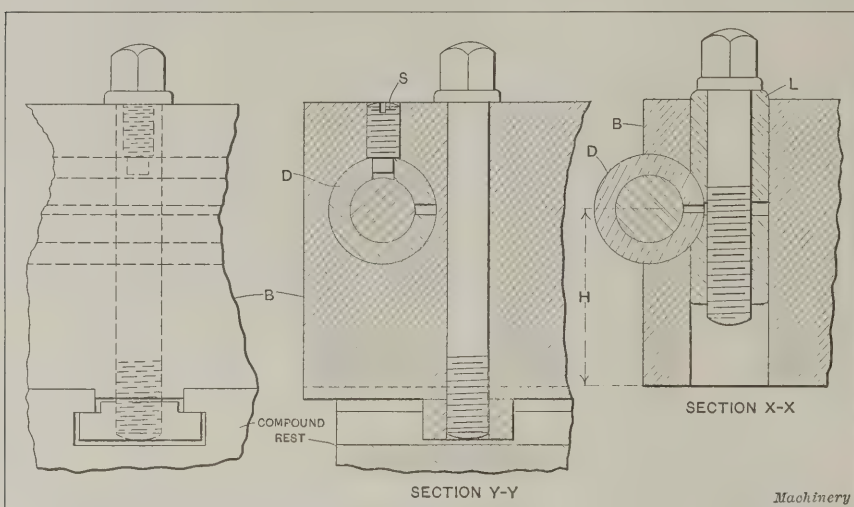

Fig. 4. Partial Side View and Sectional Views of Ellipse Turning Fixture

The compound rest is turned around to an angle a which determines the length of the minor axis of the ellipse, and is fed straight in on this angle in the operation of turning the cam. The major axis of the ellipse is determined by the diameter of the circle generated by the cutting point. The angle that determines the minor axis can be readily derived by the method shown in Fig. 5, which is merely the projection of a circle of diameter equal to the length of the major axis of the cam, at an angle sufficient to give an apparent width equal in length to the minor axis. In the triangle ABC,

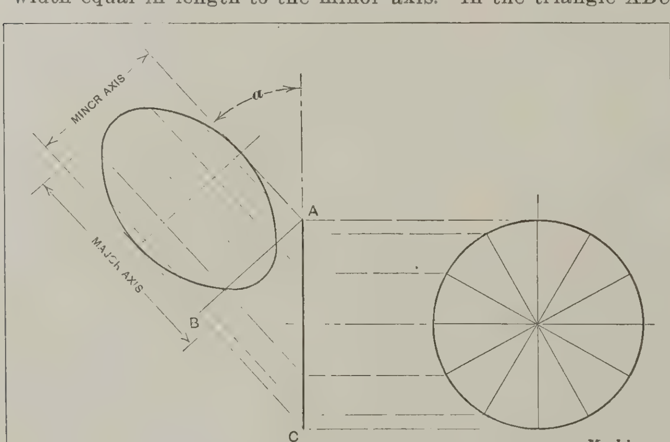

Fig. 5. Method of deriving Angle of Compound Rest

AC is equal to the major axis and AB is equal to the minor axis, and the angle BAC equals angle a. Then $\frac{AB}{AC}$ or $\frac{\text{Minor Axis}}{\text{Major Axis}}$ equals the cosine of the angle to which the compound rest must be revolved for the desired results. This method of turning ellipses could be successfully applied to the turning of the familiar oval locating plugs used in tool work, and for a variety of other classes of work.

* * *

The best all-around aluminum mixture, says a writer in the *Brass World*, is an alloy containing 92 per cent of aluminum and 8 per cent of copper. This mixture casts well, does not crystallize in service or crack in the mold, and has a fair tensile strength.

JOINT MEETING OF THE A. S. M. E. AND V. D. I. IN GERMANY

The plans for the meeting of the American Society of Mechanical Engineers with the Verein deutscher Ingenieure which have been nearly completed, promise the most remarkable tour of the industries in Germany ever offered to American engineers. Conrad Matschoss, Dozent of the Royal Polytechnic High School of Berlin, has been in the United States for several months as representative of the German Society, arranging the details of the tour. The engineers will sail for Germany June 11, and arrive in Hamburg or Bremen June 21, where they will be received by the municipal authorities and given opportunity to visit the great shipyards before going by special trains to Leipzig. There they will be welcomed by the King of Saxony and the municipal authorities of Leipzig.

The party will leave Leipzig June 25, for a tour of industrial Germany visiting the principal cities, such as Dresden, Berlin, Dusseldorf, Cologne, Frankfurt a/M, Nuremberg, Munich, etc. It is expected that the Krupp works will be thrown open to the party and that they will be received by Baroness von Bohler, daughter of the late Herr Krupp.

The final meeting will be held in Munich July 7 in connection with the Museum of Technical Arts of which Dr. von Miller is the director. The itinerary of the society in connection with the fifty-fourth annual meeting of the Verein deutscher Ingenieure, as arranged at present is as follows:

June 21.—Reception at the landing place by the local board.
June 22.—Leipzig, official reception by the Verein deutscher Ingenieure.
June 25.—Dresden.
June 27-28.—Berlin.
June 29.—Düsseldorf—Reception by the Rhine-Westphalian Section of the Verein.
June 30-July 2.—Various functions arranged by the Rhine-Westphalian section, including a trip to Cologne and Essen.
July 3.—Bonn—By boat up the Rhine with festival at Rüdesheim; by rail to Frankfurt a/M., arriving about 6 P. M.; evening reception of welcome at Frankfurt.
July 4.—Independence Day at Frankfurt.
July 5.—Nuremberg.
July 6.—Munich—Evening reception of welcome.
July 7.—Visit to the German Museum.
July 7.—Trip on the Starnberg Lake. Evening—Final exercises in the Pathaus.

* * *

EXPERIMENTAL WORK ON KEROSENE CARBURETERS

What promises to be an investigation of more than usual interest and utility is being conducted by the State Engineering Experiment Station at the Pennsylvania State College, State College, Pa., under the direction of Prof. J. A. Moyer of the mechanical engineering department. With the increase in the price of gasoline has come the demand for some cheaper fuel that will give as good results. Kerosene would meet the demands if a satisfactory carbureter could be designed, and it is with a view of determining the merits and defects of various types of carbureters that the investigation is being carried on. The price of gasoline has nearly doubled in this country in the past year, while in England the price has risen to fifty cents a gallon for "motor spirit." The use of a mixture of gasoline and kerosene has been advocated, but without an efficient carbureter no such mixture can be used. Prof. Moyer has installed at the college a motor built to utilize the energy from either of the two fuels mentioned and suitable for use on farms and country estates. Experiments will also be made on various mixtures, and a carbureter valve will be designed to shift the fuel supply automatically from a small gasoline tank, used only for starting, to the main kerosene tank.

THE ABBOTT BALL-BURNISHING PROCESS

A METHOD OF FINISHING POLISHED WORK BY TUMBLING

BY CHESTER L. LUCAS*

Burnishing, as used in the ordinary sense of the word, consists in finishing exterior surfaces of work by rubbing with a highly polished steel hand tool, which hardens and

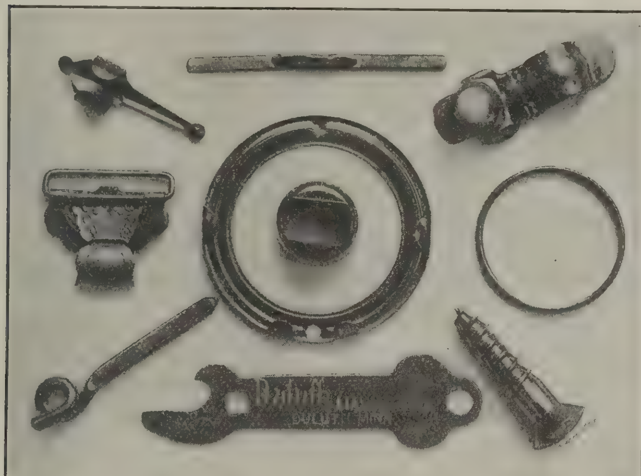

Fig. 1. Character of Work finished by Abbott Ball-burnishing Process

polishes the surface metal. The Abbott ball-burnishing process produces the same effect, but in an entirely different manner, employing quantities of hardened and polished steel

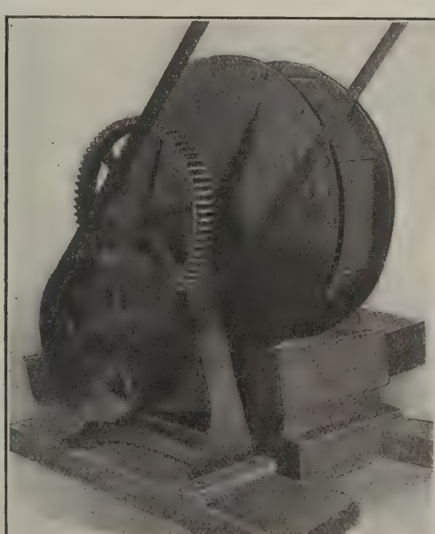

Fig. 2. Type of Burnishing Barrel used

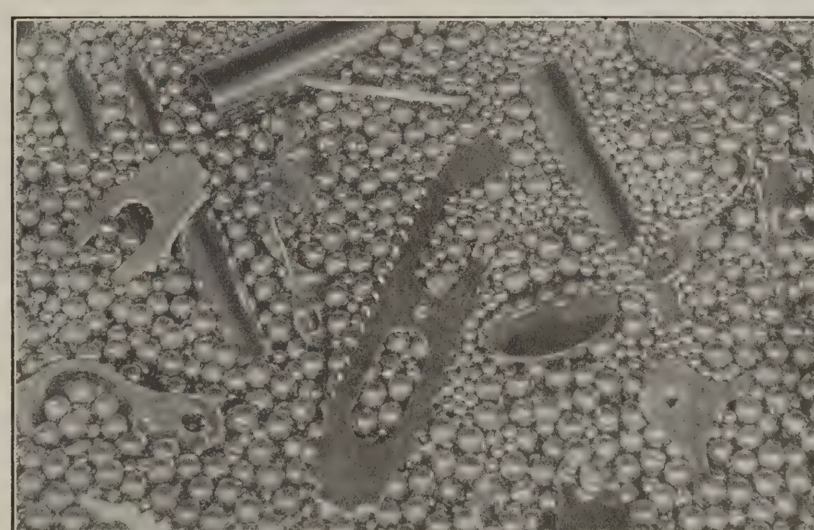

Fig. 3. View within the Barrel to show Burnishing Action of the Balls

balls which are caused to roll over the work while under pressure. This pressure is effected by the weight of the balls which are confined within a tumbling barrel like that shown in Fig. 2. Thus, each ball acts as an individual burnishing tool, and as it rolls over the work, pressed by the mass of balls and work above, it leaves a burnished path on the work. Fig. 1 shows some representative burnishing jobs which have been efficiently handled by this process. Some idea of the action which takes place within the tumbling barrel may be gathered by noticing the balls and work which are represented in Fig. 3.

Fig. 4 shows the general form of the ordinary tumbling barrel as contrasted with the Abbott burnishing barrel. From this it will be seen that in the Abbott barrel, the balls are confined in a deep narrow space so that the same amount of balls being restricted within a narrower space exert a heavier burnishing pressure upon the work. The Abbott ball-burnishing process cannot be used when any metal is to be removed or deep scratches are to be taken out. It is purely and simply a burnishing process for putting a high finish upon the work, and on work within its limitations is highly successful. Not only can a large amount of work be done in a short space of time, and in a very efficient manner, but many jobs which cannot be burnished by hand are efficiently finished by this process. Referring to Fig. 3 again, it will be seen that it is a simple matter for the balls to burnish the inside of a tube, the center of a deep depression, or the inside of a wire loop as shown in Fig. 1. Such pieces as these would be difficult to burnish in any other way. In order to burnish corners and depressions, it is necessary to employ balls small enough to come in contact with the surfaces of such places; therefore, on other than the very plainest of work, two sizes of balls are commonly used as shown in Fig. 3. Again, on work which is lettered, ordinary polishing processes "drag" the letters, but with the ball-burnishing process, this trouble is not experienced.

The balls used for this work are made of low carbon steel, by the heading process, carbonized and hardened clear through and then highly polished. The balls are not truly spherical, nor of an exact size, but they are highly finished and very hard. The barrels may be of the single or multiple type, having one or more compartments. The barrel shown in Fig. 7 has two sections, and gives a general idea of the construction. The compartments are octagonal in shape and are lined with maple wood so that the balls and work do not come in contact with any metal during the burnishing process. Two hand-holes are provided for each compartment with covers which may be clamped in place. The two hand-holes furnish a means for quickly removing the contents and washing out the barrel. A lubricant is employed in burnishing, which ordinarily consists of soapy water.

To burnish a quantity of work, the work and balls are

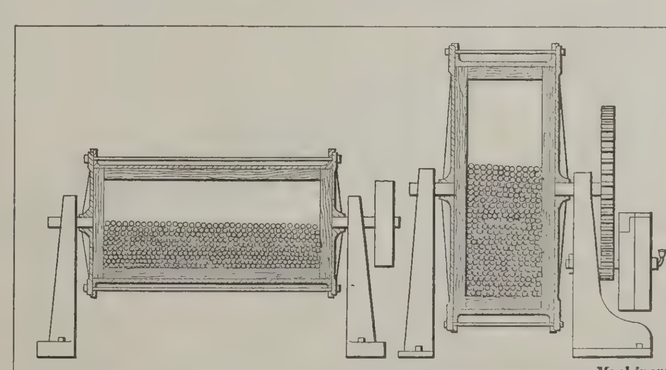

Fig. 4. Comparison of Old-style Barrel with Abbott Barrel

placed in the barrel in the proportion of one peck of work to two pecks of steel balls. Water is then added until it stands about one inch above the contents of the barrel. In this water, about four ounces of burnishing soap chips have pre-

* Associate Editor of MACHINERY.

viously been dissolved. The hand-hole covers are then clamped in place, and the mixture tumbled from one to five hours, depending upon the character of the work, metal, etc. The speed ordinarily employed for tumbling ranges from 10 to 30 R. P. M., the usual speed being 15 R. P. M. If after tumbling, the work has a dull or smutty appearance, the soap solution should be drained from the work and clean water substituted, to which should be added a piece of cyan-

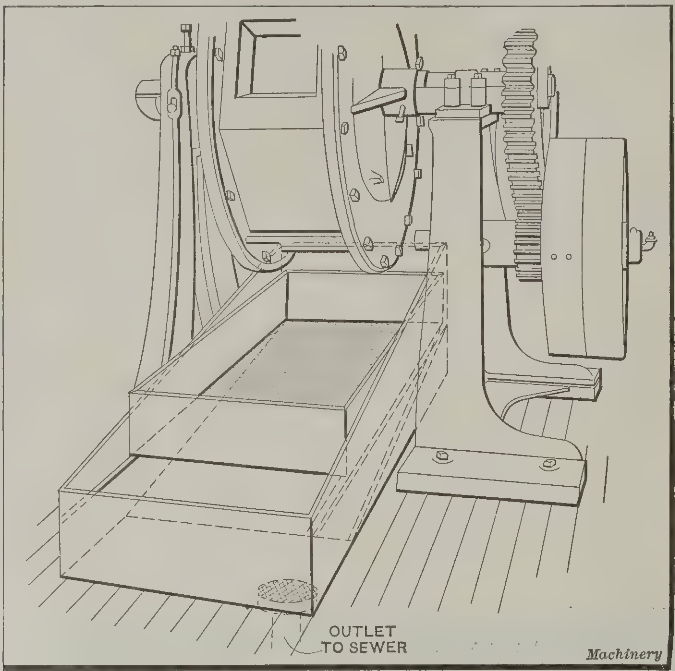

Fig. 5. Convenient Arrangement for Separating Balls and Work

ide of potassium about the size of a pea. It is highly important that the balls be kept from rusting, for rust, of course, destroys their burnishing qualities. The balls are easily kept in good condition by returning them to the barrel with the soap solution on them, but in no event should they be washed in clear water and allowed to stand. The burnishing operation is the same on all kinds of metal. After the work has been burnished sufficiently, it is separated from the balls by dumping the mixture into a screen of sufficiently coarse mesh to allow the balls to drop through. A convenient arrangement to use for separating the balls from the work is shown in the illustration Fig. 5.

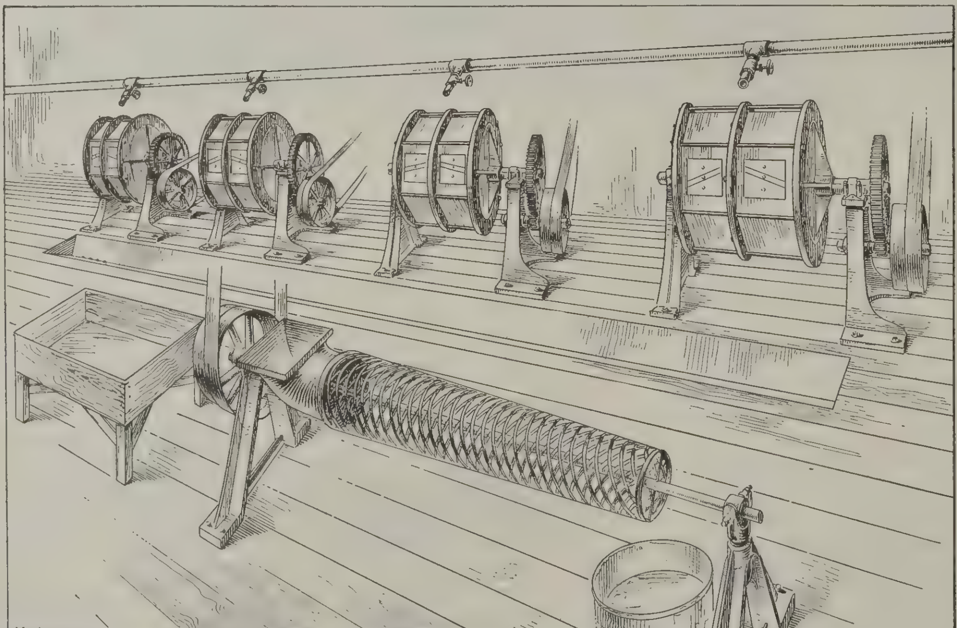

Fig. 6. Abbott Ball-burnishing Installation at Heron Mfg. Co.'s Plant

If the work is not to be plated, it is taken from the barrel and dried in sawdust, but if to be plated, it is cleaned in the usual manner and plated. The cleaning operation incident to plating is usually very troublesome on account of the rouge that is driven into corners of the work by the polishing wheels. No such trouble is experienced after ball-burnishing, as no rouge is used. It is only necessary to rinse off the soap solution, dip in potash and plate. After plating, the

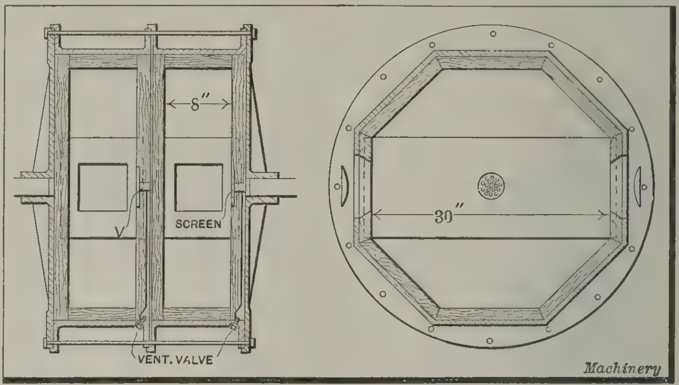

Fig. 7. Construction of Ball-burnishing Barrel

work is returned to the barrel and tumbled in a soap solution for a half hour to impart a high finish.

While most commonly used for small work, say under three inches in greatest dimension, larger work may be handled

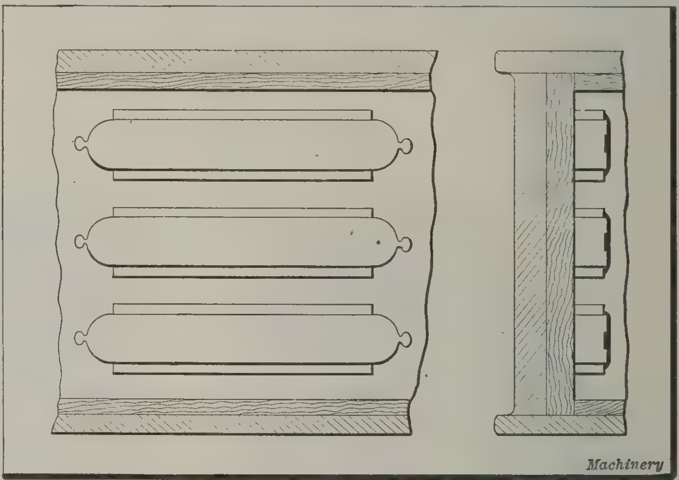

Fig. 8. Section of Barrel to show Method of Mounting Large Work

by a modification of the process. The difficulty in burnishing large work is due to the fact that the weight of the piece is often great enough to injure other pieces of work, and, of course, if the pieces are easily bent, there will be trouble from this source. Aside from the danger of bending large work in the burnishing barrel, a greater source of trouble is from scratches caused by the sharp edges of such pieces coming in contact with the finished faces of other pieces in the barrel. Referring to the illustration Fig. 8 a method of mounting pieces of this character is shown. Any convenient method of clamping is employed, depending, of course, on the shape of the pieces, but the fundamental idea is to support the pieces so that they cannot move in the barrel, and yet give the burnishing balls a chance to act upon the work exactly the same as though it was loose in the barrel. Mounted in this manner no possible injury can be done to the work and yet the balls have access to every part of the piece except the edge, even to the inside. It is apparent that this method cannot be used for all work, but a little ingenuity will often solve the problem without having to resort to hand polishing.

A typical installation of the Abbott ball burnishing process is found at the Heron Mfg. Co., Utica, N. Y. This installation

is represented by the illustration Fig. 6, in which are shown four double barrels driven from a common shaft. A line of piping extends over the four barrels, being connected with a hot water tank on the floor above. By means of outlets over the barrels, water may be admitted to the barrels for mixing the burnishing solutions, and for cleaning the barrels and their contents after the burnishing operation. A trolley system is arranged so that after the work has been dumped from a barrel into a basket, during which operation the suds and soap solution are carried away by means of the trough in front of the barrels, the work may be carried to the sawdust box for drying. This sawdust box is of the usual type and after the work has been sufficiently dried, it is shoveled into the chute shown at the right of the sawdust box, from which it enters the revolving conical screen cylinder and is separated from the sawdust, emerging from the small end of the screen, completely dried and ready for shipment.

By the use of this apparatus, the Heron Mfg. Co., who manufactures casters of all kinds, states that it is producing twice the number of parts at half the cost, and getting a better finish than when using hand polishers. Thus an expensive polishing and buffing equipment is eliminated, as well as the high priced labor formerly employed.

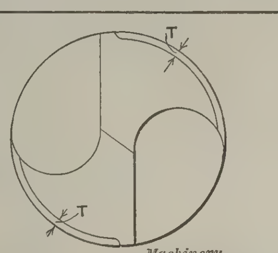
CLEARANCE ON TWIST DRILLS

In the June, 1911, number of MACHINERY an article was published entitled, "Data for Fluting and Relieving Twist Drills," which gave the dimensions of the fluting cutters used for grooving twist drills and also the thickness of the web and the width of the land (portion not relieved) on twist drills. The accompanying table gives the total amount of clearance, $2T$, for twist drills, as made by a prominent maker, the illustration showing how the dimension T is measured. The clearances given are for the finished drill sizes. Of course at the time the clearance is milled, the unrelieved portion of the drill is still a certain amount over the finished size. The amount of "oversize" must, of course, be added to the dimension T to determine the clearance in the unfinished drill. When measuring the depth of the clearance, the diameter is measured by micrometers over the relieved part. The dimension thus measured is the finished diameter of the drill less twice the dimension T. The thickness of the web as given in the June, 1911, number of MACHINERY is that at the point of the drill. Most makers groove their drills on a taper, which is so selected that the web is about forty per cent thicker at the upper end of the groove than at the point.



AMOUNT OF CLEARANCE ON TWIST DRILLS

Size of Drill, No.	Total Clearance, 2 T	Size of Drill, Inches	Total Clearance, 2 T	Size of Drill, Inches	Total Clearance, 2 T	Size of Drill, Inches	Total Clearance, 2 T

3– 1	0.015	31/64	0.032	1	0.057	3 1/2	0.085

The allowance made for grinding varies with different manufacturers from about 0.010 to 0.015 inch. When high-speed steel is used, 0.025 inch is allowed for grinding on account of the scale produced in hardening. Straight drills smaller than from about 3/8 inch to 1/2 inch are not ground after hardening, as they are made from drill rod of the correct size. On the larger sizes, however, there is considerable decarbonization of the outer shell, and it is advisable to make an allowance for grinding on all drills larger than 3/8 inch diameter, which, in fact, is the practice of many of the twist drill makers.

* * *

LIFE AND COST OF PATENTS

In an article in *Engineering* (London) of October 18, Mr. G. G. M. Hardingham gives a table stating the number of years during which patents are valid in various countries, and the total patent office fees paid for maintaining a patent during the specified number of years. It will be seen that in most countries the fees, which are given in the English monetary system the same as in the original table, are very much higher than those in the United States. It should be understood, however, that the large sums mentioned for some of the European countries are not payable in total at the time when the patent issues. In many countries yearly dues are payable in order to maintain a patent once issued. All these yearly dues have been added together so as to show the actual cost of a patent running for a specified term of years. Under the influence of the patent renewal fees in force in most European countries, a great many patents are annulled after they have been running only a few years, due to the fact that renewal fees are not being paid for them. In Great Britain, for example, statistics show that an average of 66.4 per cent of all the patents actually issued are annulled at the end of the fourth year, when renewal fees commence to become payable. Only 14.9 per cent of the total number of patents are renewed at the beginning of the eighth year; 7.6 per cent are renewed at the beginning of the eleventh year; and only 3.2 per cent run for the full term of fourteen years. It has been argued that patent renewal fees of some kind are desirable for the purpose of weeding out useless and unworked patents, but the correspondent of our contemporary, whose table is quoted, points out that there are two sides to this question. The table itself, however, is interesting as showing how cheaply a patent may be obtained and maintained for a period of seventeen years in the United States, as compared with the cost in the leading European countries. It also, probably, explains why the number of patents issued in the United States exceeds to such a large extent those issued in the other leading industrial countries.

TABLE SHOWING LENGTH OF TERM OF PATENTS AND TOTAL FEES IN VARIOUS COUNTRIES

Machinery

LETTERS ON PRACTICAL SUBJECTS

We pay only for articles published exclusively in MACHINERY.

COMMENTS ON QUARTER-TURN BELTING ALIGNMENT

In reading Mr. M. H. Ball's article on quarter turn belting alignment in the September issue of MACHINERY, the writer is reminded of an incident which occurred some twenty-five years ago. A millwright was sent from a machine shop in central Massachusetts to install a water wheel and all of the power transmission equipment for a large mill in Maine. Included in the job there was a quarter-turn belt, 16 inches wide, that ran through five floors from the basement to the upper story. From the time he began the job, which was of some three months' duration, the quarter-turn belt was in the millwright's mind, as he had not the least idea how to install it. However, it was up to him to do it some way, and all his spare time was devoted to studying the matter. It may be said, in passing, that he had not a technical education, and therefore had no knowledge of descriptive geometry, but as the floors were all laid with hard pine tops, he did not want to cut belt holes big enough to let a wagon and oxen through. After studying the problem for some six weeks, the millwright went home for the express purpose of asking the boss how to lay out and cut the belt holes. The answer he received was, "If the pulleys were of the same size with only a single floor located midway between them, I could tell you; as it is, I don't know how." So the millwright returned to the job no more enlightened than when he left.

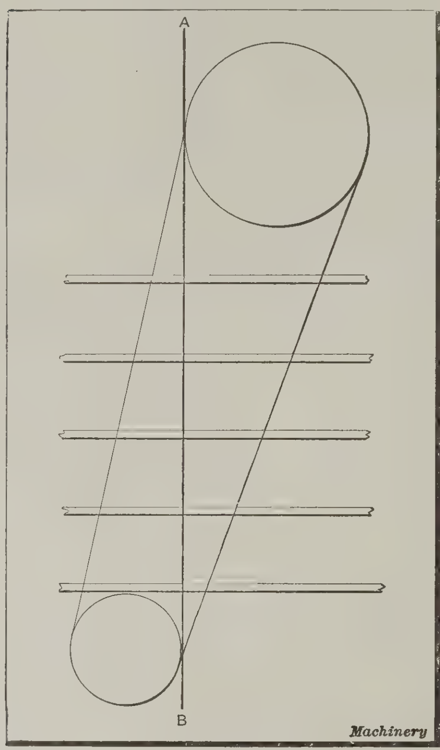

Diagram for laying out Belt Holes

One evening he took a compass and struck two circles to represent pulleys of different diameters, one above the other; he then drew lines representing an open belt from one pulley to the other, a line from the left of the upper pulley to the right side of the lower pulley, and lines to represent the five floors, as shown in the illustration. After studying over the sketch for some two hours or more the millwright was about to give it up for the night. He took up the paper and started to fold it on the line *AB*—purely mechanically—without any purpose whatever in doing so, but still thinking hard of the subject which had troubled him so long. He raised his hand to throw the paper into the fire, when it opened at an angle of about ninety degrees and caught his eye. He stopped and looked first at one side of the fold and then at the other, and was astonished as well as delighted to see that the solution of the whole problem was before him—perfectly plain and easy to understand. The line *AB* represented the plumb line through the floors, from the face of the upper to the face of the lower pulley, and the lines representing the belt showed the distances of the belt from the plumb line each way, and also the angle which the belt made in passing through the floors. The next morning the millwright made a drawing of the same thing to scale, and then to be absolutely sure, he made a model to the same scale, cutting all the belt holes, and putting on a model belt. He then laid out all the belt holes, allowing half an inch all around, and when the belt was put on it did not strike the side of any one of the holes. The writer believes that this incident shows what persistent thought and study will accomplish under most unfavorable circumstances.

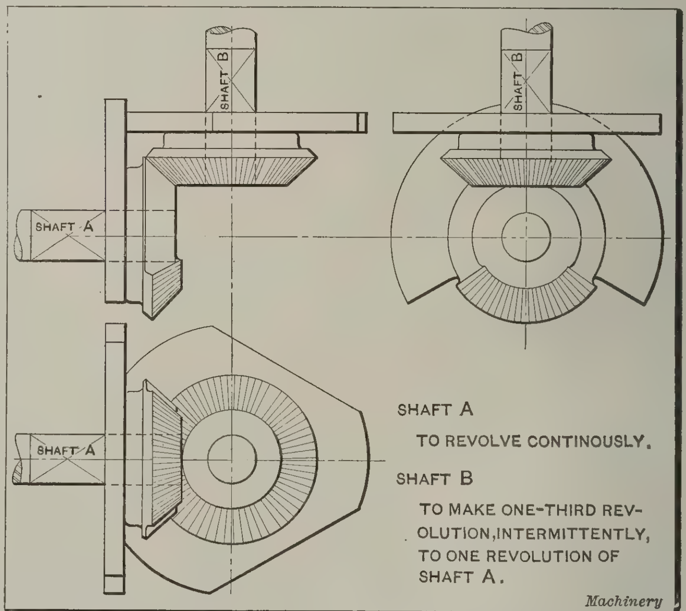
S. S. JENNISON

Cleveland, Ohio

AN INTERMITTENT MOTION

The feed rolls of machines for making cardboard fillers for egg boxes require an intermittent motion for their operation. They feed cardboard into the machine while in motion, and hold it for cutting while at rest. In one case a continuously running shaft was made to give this motion through an ordinary miter gear and a properly proportioned miter gear sector. This sector engaged and turned the miter gear during one-third of a revolution and then allowed it to remain idle during the remaining two-thirds. In the design of the machine no provision was made for keeping these ratios exact, further than by correctly proportioning the gears. As a consequence of slight variations, this combination gave much trouble through the gears not meshing correctly. This caused the gears to be broken, the timing of the feed to be destroyed, and the working of the machine to be generally deranged.

The illustration shows the method used for overcoming these defects and obtaining an accurate and sure-working feed



Mechanism for regulating Action of an Intermittent Motion

motion. It consists of a pair of flat plates attached to the shafts *A* and *B* behind the gears. The plate carried by shaft *B* is slabbed off on the three sides of an equilateral triangle. to give the correct dimension from center to edge, and the plate carried by shaft *A* is cut away to allow clearance for the plate on shaft *B* while turning. The mechanism acts exactly as before, except that when shaft *B* is idle, it is held in place by the bearing of one plate on the other. These plates limit the movement of shaft *B* to exactly one-third of a revolution for each revolution of shaft *A*. The former difficulties are thus remedied, and a smoothly running machine made possible.

MILES SAMPSON

Manchester, N. H.

ATTACHMENT FOR WINDING CLOSE COILS IN SPRINGS

The spring winding attachment shown in Fig. 1 is designed to fit on the back end of an ordinary lathe headstock. The attachment can be set to produce from one to two and one-half

close coils, at required intervals, so that a spring of the full length of the lathe can be wound and then cut up into lengths. This method of close coiling makes it possible to save the time that was formerly taken in closing the ends by hand or in heating the ends of larger springs before closing them up.

The attachment is driven by the screw cutting stud, through the regular change-gears, to the lead-screw, as in an ordinary screw cutting operation. The nut is kept in engagement with the screw all the time. The change-gear is loose on the screw cutting stud, but has a clutch member keyed to it; the other part of the clutch is keyed on the stud and has a spring to push it into engagement. When these two clutch members are in engagement the apron travels forward; when the clutch

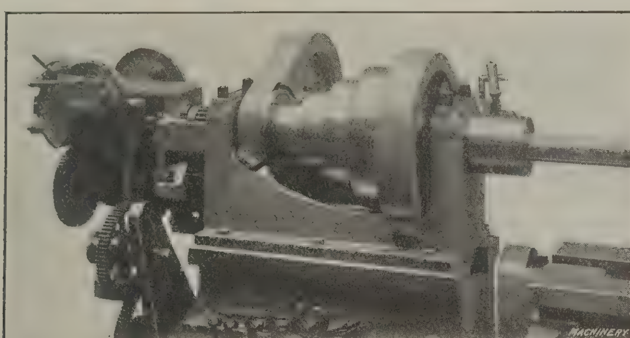


Fig. 1. A Lathe Attachment for winding Springs

is disengaged the apron stands still but the spindle continues to revolve.

The screw cutting stud is continued outward and drives a cam A by means of two gears, as shown in Fig. 2. This cam runs continuously and acts on a runner attached to the curved lever B which carries a spring plunger or pawl C. Each time the lever reaches the top of its stroke, the pawl carried by it acts on the ratchet wheel and picks one tooth. The ratio of the gearing which actuates the cam is such that it requires three strokes of the lever for each two coils of spring which are wound. The ratchet wheel is prevented from coming back by means of the fixed catch D at the top, which holds it against the weight and rope tending to pull it back. On the side face of the ratchet wheel there is a T-groove in which a dog is clamped. As soon as the ratchet wheel has been advanced through the required distance, this dog comes against a projection E on the inside of the ratchet mask; the ratchet and mask then travel together. The mask has a gap through which the pawl usually works; consequently it remains stationary until it is engaged by the dog on the ratchet wheel. This mask is rather larger than the ratchet wheel, the bottom of its teeth being slightly above the top of those on the ratchet, so that when it begins to move, the pawl C and fixed catch D are both lifted out of contact with the wheel and allow it to go back under the pull of the rope and weight.

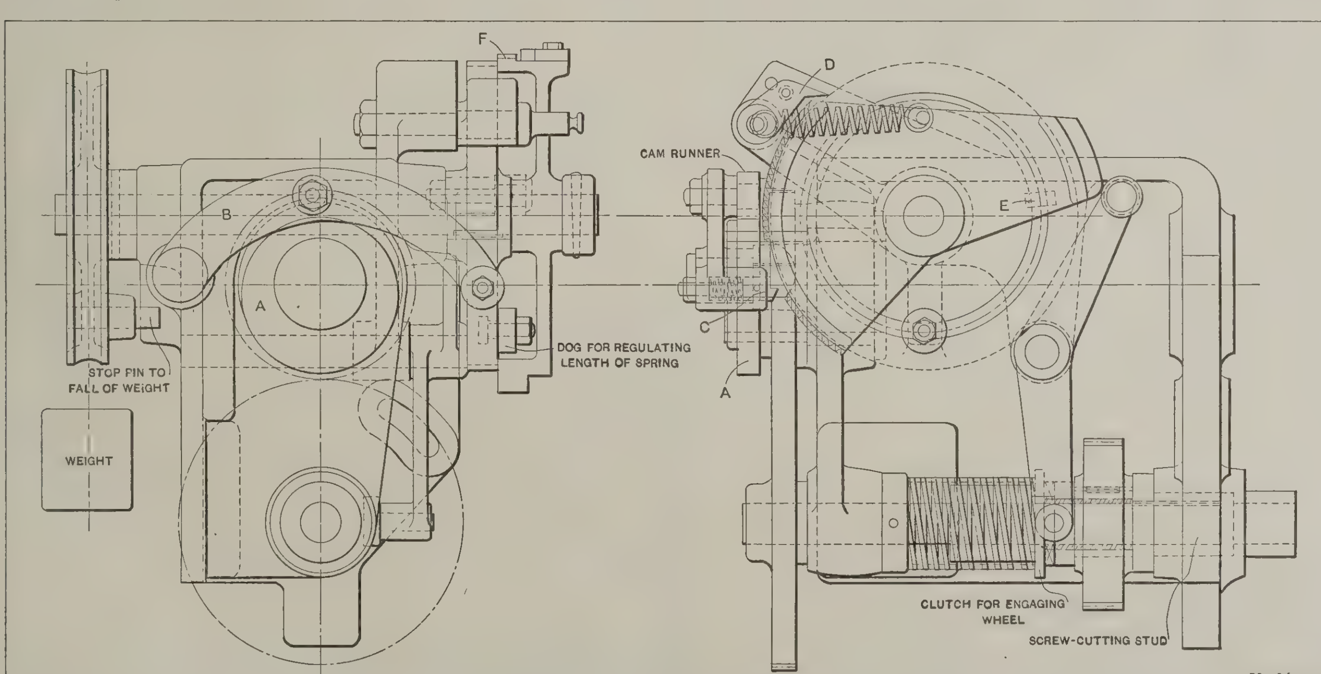

Fig. 2. Details of the Mechanism for producing the Close Coils

Shortly after the mask begins to move, its corner comes in contact with the cam runner on the lever which controls the stud clutch. This throws out the clutch and stops the travel of the apron. The mask continues to rotate through the action of the pawl until it has produced the required number of close coils. An adjustable dog for lifting the catch now comes into action and throws the catch out of engagement with the mask; the tension of a spring then returns the mask to its original position. This releases the clutch lever and allows the drive on the screw cutting stud to be reengaged. At this point, the apron continues its forward movement for the production of another section of the spring. When the mask is returned, the fixed dog, which it carries, pushes the retaining catch into engagement with the ratchet wheel, thus restarting the latter in rotation.

Means are provided to cushion the weight so that the full shock does not come on the attachment. Suitable means have been taken to adjust the ratchet pawl so that it takes only one tooth at a time, also to have it drop clear of the ratchet wheel in order that the latter may be given time to run back when the action of the weight becomes effective. The design of the teeth of the clutch on the screw cutting stud must be such that they will have plenty of clearance and not too strong a spring behind them, as this would make the return uncertain.

The pitch of the spring is obtained in exactly the same way as the pitch of a screw produced in the ordinary manner. The attachment merely determines the length of each section of the spring and the number of close coils that are to be produced.

Keighley, England W. Haggas

CASEHARDENING PRACTICE—A COMMENT

The writer would like to make a few friendly criticisms and comments on Mr. Robert Grant's article on "Casehardening and Casehardening Practice" in the October number of Machinery. In the first place, the general methods outlined are not entirely in accordance with the most modern practice. However, the article is good and in most cases it treats of the present methods practiced all over the country.

The statement is made that carburized steel should never be quenched at the carburizing heat, but should be cooled to the hardening heat, as the latter is much lower than the carburizing heat. This would make little improvement, for the grain of the steel would be about the same as if it had been quenched at the highest temperature attained while

carburizing. It is necessary to cool the steel below its lowest critical point (about 1275 degrees F.) and then reheat it to the hardening temperature, thus quenching on a rising heat, in order to secure a refined grain. Steel should never be quenched on a falling heat.

Mr. Grant's method of local hardening is not the most modern, and it is expensive and troublesome. He shows a cup-shaped piece in Fig. 6, which was only hardened at the interior of the cup, using another cup-shaped piece to prevent the outside from hardening. There is now a prepared fire paint on the market which works admirably when painted on parts of steel that are not to be hardened. This paint is in the form of a powder and is mixed up with water to the consistency of paste; it is then ready to be applied. The steel can be painted before or after carburizing. If painted before, the part of the steel which it covers will not be carburized, and consequently it will not harden. If the paint is applied after carburizing, the painted steel will not harden, although it is carburized, because the paint forms a shield which does not let the water come in contact with the steel. This makes local hardening a simple proposition, and is superior to copper coating. The use of the mandrels shown in Fig. 5, for preventing the hardening of the inside of rings, could be done away with by using this fire paint. The fire paint is also useful in corners where a thin part joins a thick part in the steel, the paint forming a fillet that leaves the corner soft after hardening and prevents breakage.

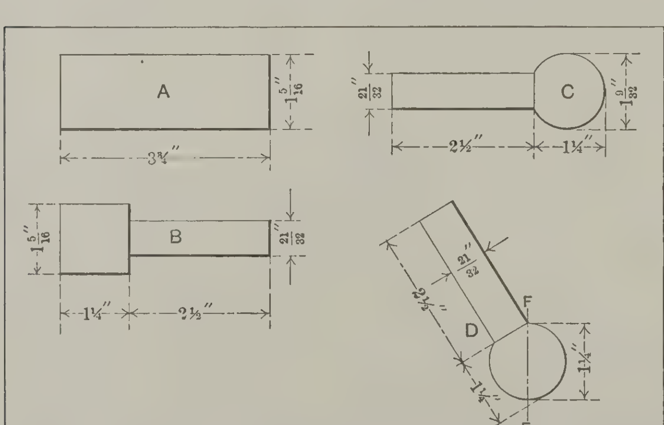
Mr. Grant says that small pieces packed in a box for carburizing may touch each other without detriment. It is hardly possible that this would be true in actual practice, because the surfaces in contact would prevent direct contact of the carburizing material; therefore these spots would get little or no carbon, and the steel would either have soft spots after quenching or the depth of case would be irregular.

The method of drawing the temper of hardened steel by heating it in a muffle is not nearly so reliable as drawing it in oil, where the temperature can be accurately gaged with a thermometer. Drawing in oil is a more rapid and accurate method. Mr. Grant says that large articles require a higher carburizing heat than small ones. The writer does not see the reason for this. Of course it takes a higher heat to penetrate a large piece in the same time as a small one, but it seems that if two pieces of steel—one small and one large—are held at the same uniform heat for the same interval of time, they will each receive the same depth of case.

Cleveland, Ohio J. E. WASHBURN

TURNING SPHERICAL SHAPES BY HAND

Special fixtures and methods for ball turning have been shown and described in recent issues of MACHINERY. The accompanying illustration shows a method which the writer



Successive Operations in Turning Ball-shaped Parts by Hand

recently used in a job shop where no ball turning device or lathe with a compound rest was at hand. The pieces to be turned up are stub ends to be welded onto the steering arms of automobiles for repairs. After cutting off the pieces, as shown at *A*, they were faced to the proper length and centered, and were then caught in a three-jaw universal chuck and one end was turned down, as shown at *B*. The pieces were then reversed in the chuck and the ball shape was roughed out by hand as accurately as practicable, as indicated at *C*. They were then caught in the chuck in the position shown at *D*, on the points of the chuck jaws, so that a circle could be turned to 1¼ inch diameter along line *EF*. Preferably, this should be done in an independent jaw chuck so that the circle turned in this position will agree as nearly as possible with the diameter marked 1 9/32 inch, previously turned. The pieces are then returned to the position shown at *C*, and the ball is finished, the circle turned to 1¼ inch diameter being used as a "witness" mark. H. W. RICKS

Santa Ana, Cal.

TURNING A BALL WITHOUT CENTERS

It was required to turn the brass ball shown in Fig. 2 without the use of centers, and in performing this operation the following method was used. A 4-inch bar was chucked in the lathe and the ball roughed out. The compound rest was next set with the pivot directly beneath the center of the ball and slowly swung around to form the work. The tool was fed in until the caliper showed that the ball had been reduced to

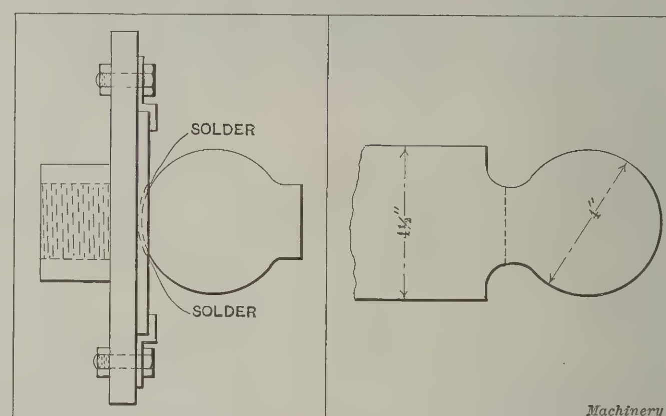


Fig. 1. Method of securing Ball to Faceplate Fig. 2. Ball ready to be cut from Bar

the required diameter of 4 inches. This turning operation was continued until the work had been brought to the form shown in Fig. 2. The ball was then cut off along the dotted line leaving sufficient stock to finish.

The chuck was next removed and a faceplate mounted on the lathe spindle in its place. A brass plate was then strapped to the faceplate and a hollow was turned in it with the tool in the compound rest. The same radius was used for this purpose and, consequently, the hollow formed was of exactly the right size to hold the ball. The work was then mounted in the position shown in Fig. 1 and the tailstock brought up against it to secure it in place. Soft solder was now melted into the joint between the ball and disk, a blow torch being used for this purpose. This method of fastening proved entirely adequate to hold the work in place after the tailstock had been removed. The remaining surface of the ball was then finished. In performing this operation, it was necessary to maintain exactly the same radius on the compound rest, but this did not interfere with the possibility of moving the rest along the lathe bed to bring it into position for completing the ball.

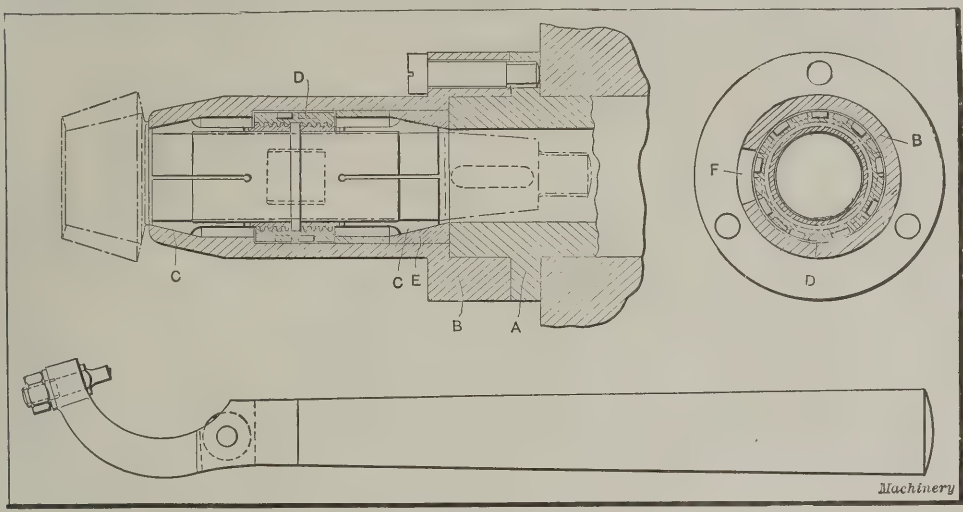
The advisability of turning balls in this way may be questioned, as some may regard the method of turning them between centers and then grinding off a more rapid process. This is true in some cases, but for the operation described in this article it was necessary to have the ball accurate to 0.0001 inch, and the method described enabled the work to be produced to meet this requirement.

New Britain, Conn. J. M. HENRY

DOUBLE GRIPPING CHUCK

In the shops where the writer is employed we had to rough out some very hard nickel steel miter gears on a spur and bevel gear cutting machine. The usual chucking devices at our disposal failed to do their duty, as we could not possibly take the heavy cuts without moving the work.

The double gripping chuck shown in the accompanying engraving was, therefore, designed and proved quite effective. At *A* is shown the machine spindle; *B* is the chuck which is firmly fastened to the spindle by means of three screws. At *C* are shown two conical split collets which are fitted on the inside of the chuck, the front one resting in a taper seat, while the rear one rests in a ring *E* held against the front of the machine spindle. Both collets are threaded on the outside with a right- and left-hand thread, respectively, and are screwed into a ring *D* which holds them together. The ring has, on the outside surface, spanner holes so arranged in two rows around the circumference, that when the ring is rotated they alternately pass in front of a rectangular opening *F*.



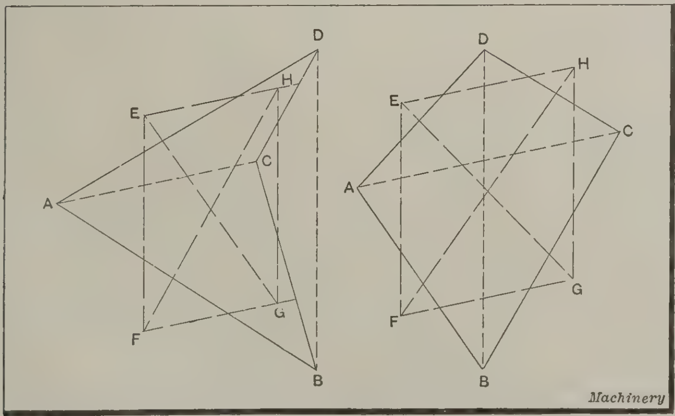
A Special Double-gripping Chuck

Through this opening the tooth of the spanner shown in the lower part of the engraving is inserted. Ring *D* is thus rotated, and the two collets *C* operated against the taper surfaces, so as to clamp the work firmly in position.

Turin, Italy. G. Boella

FINDING THE CENTER OF GRAVITY OF ANY FOUR-SIDED FIGURE

In many calculations pertaining to the design of machinery, it is necessary to find the center of gravity of irregular polygons, and the following is a simple method of obtaining the center of gravity of any four-sided figure. Two cases are possible, as shown in the illustration. To find the center of gravity of the four-sided figure *ABCD*, each of the sides is



Method of finding the Center of Gravity of any Four-sided Figure

divided into three equal parts. A line is then drawn through each pair of division points next to the points of intersection *ABCD* of the sides of the figure. These lines form a parallelogram *EFGH;* the intersection of the diagonals *EG* and *FH* locates the required center of gravity.

McKees Rocks, Pa. August H. Anger

[To prove that *EFGH* is a parallelogram, a line is drawn connecting points *B* and *D*. This forms two triangles *BCD* and *BAD* having the common base *BD*. It can be shown that a line which subdivides any two sides of a triangle proportionately is parallel to the third side. The line *EF* divides the sides *BA* and *DA* in the ratio of 2 to 1, and so it is parallel with *BD*. The line *GH* divides sides *BC* and *DC* in the ratio of 2 to 1, and so it is parallel with *BD*. Hence the lines *GH* and *EF* are parallel to the common line *BD* and with one another. To prove the sides *EH* and *FG* parallel with one another, a line is drawn connecting points *A* and *C*. The same method will then show that the lines *EH* and *FG* are parallel to the common base line *AC* and, consequently, to one another. Hence *EFGH* is a parallelogram.—Editor.]

ERASING INK MARKS FROM TRACINGS

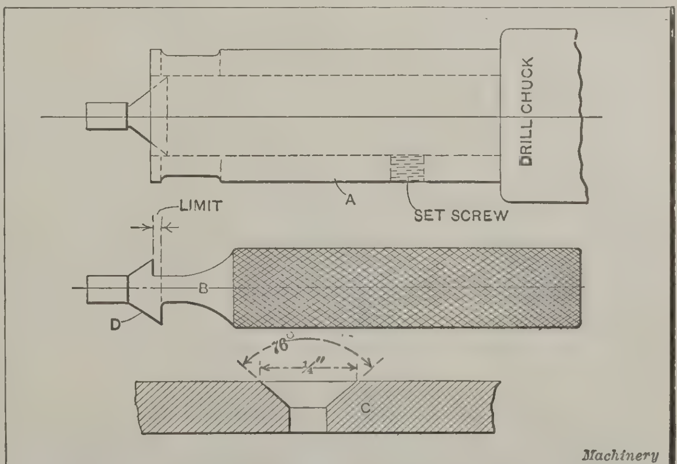
The writer, a draftsman of twelve years experience, has read many articles on the well worn subject of "Erasing Ink Marks from Tracings," but has seen nothing that agrees entirely with what he has found to be the most satisfactory method. To begin with, an ink line is one of considerable breadth and thickness. When an eraser is applied it grinds the ink up into minute particles, which are worked into the cloth as soon as the glaze is broken; these particles of ink are only removed by much unnecessary rubbing. The following is a more satisfactory method:

Place a triangle or other hard, smooth surface beneath the line or spot that is to be erased from the tracing cloth; then with a very sharp knife remove the ink which lies on top of the cloth. This means the ink which has not actually sunk into the cloth; do not scratch into the cloth. If sufficient care is exercised, the knife need scarcely break the glaze. Then, still keeping the triangle under the tracing and using a hard pencil eraser—do not use an ink eraser—it will be found that the remainder of the ink can be completely removed with little injury to the cloth. By this method, the troublesome grit coming from an ink eraser is avoided, and by applying a small amount of soapstone, the surface of the cloth is renewed sufficiently to prevent the pores filling up with dust and becoming unsightly. As a general thing, a knife is tabooed as an eraser, and with good reason, but when used according to the method outlined, the writer has found it far superior to an ink eraser.

Auburn, N. Y. Raymond H. Farwell

STOP-SLEEVE AND GAGE FOR COUNTERSINKING

The writer has had considerable difficulty in accurately countersinking holes in thin sheet metal; hence, a gage or stop-sleeve was finally devised which answered the purpose



Stop-sleeve and Gage for Countersunk Holes

so well that a description of it may be of interest to others who may have met with trouble of the same kind. The countersinking of holes in sheet metal to a uniform depth com-

bines the difficulties of ordinary countersinking with the additional difficulty that the sheet metal is apt to spring away somewhat from the tool. Trouble is also met with on account of slight bends in the sheet.

The stop shown at *A* in the accompanying illustration is a sleeve which is placed over the countersink. The top of the sleeve fits against the face of the drill chuck and is prevented from falling off the tool by a set-screw. Openings near the bottom provide an outlet for the chips. The bottom face of the sleeve is hardened and slightly drawn. It is then polished as smoothly as possible with fine emery so that it will not mark the stock. When the countersink has reached the proper depth, the face of the stop will revolve on the stock and thus prevent the tool from entering further. The pressure on the sleeve will tend to straighten out any bends in the sheet metal and make certain that every hole will be countersunk to a uniform depth.

A test gage for countersunk holes which may be of interest is shown at *B*. It is provided with a pilot for entering the drilled hole. One side of the gage proper is ground away, as indicated, to a level lower than that of the other side. In this way, the allowable limit of variation in depth of the countersunk hole is given on the gage in a very convenient way. The part *D* is ground and by using Prussian blue or red lead in gaging, the angle of the countersunk hole can be easily tested.

Many draftsmen when dimensioning a countersunk hole give its depth. This is not a convenient dimension for the shop men to work from, as it is practically impossible to measure the depth accurately without a gage; hence, countersunk holes should be dimensioned as shown at *C*, the diameter at the top and the angle being given. F. A. PARSONS

Milwaukee, Wis.

JIG FOR DRILLING HOLES CLOSE TO A SHOULDER IN SCREWS

A jig for drilling holes close to a shoulder in a screw is shown in Fig. 2. The hole to be drilled is for the threading tool to run into, when cutting threads up to the shoulder on

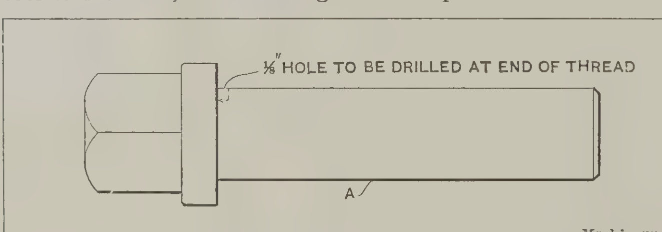


Fig. 1. Screw to be drilled

the screw shown in Fig. 1. The jig is placed in the tailstock of a lathe, and the drill is held in a chuck in the headstock.

In operation, the body *A* of the screw, Fig. 1, is held with the left hand in the V-part of the jig, with the shoulder against the

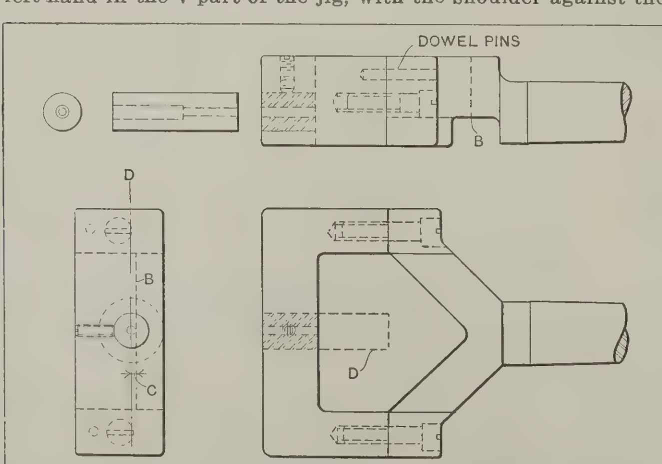

Fig. 2. Jig used for drilling Holes close to Shoulders in Screws

cut-away portion *B* (the face *B* is equal to the radius of the drill or the distance *C* from the center), while the right hand is used to run the tailstock spindle out, or, in other words, to feed the work against the drill.

In this jig the work is quickly done with a sufficient degree of accuracy, and if the drill used is ⅛ inch in diameter, screws of ⅛ inch pitch or less and of various diameters can be drilled, which makes this a handy jig for drilling odd half-dozen lots, as well as a greater number of pieces.

The long bushing *D*, shown in Fig. 2, is for supporting the drill on small diameters, as it projects further through the cap, as shown by the dotted lines. M. F.

A SWAGING OPERATION

In swaging the piece *A* to the shape *B*, Fig. 1, and in other similar work, trouble is often experienced in obtaining a satisfactory means of locating the work, owing to the flash which spreads entirely around the piece. In Fig. 2 is shown

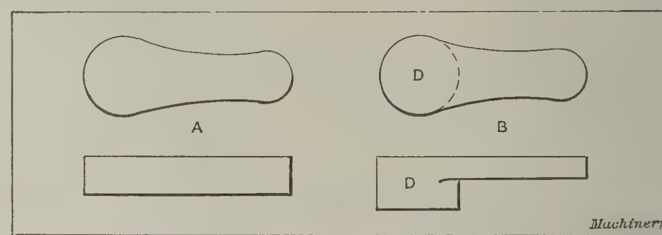

Fig. 1. Piece of Work before and after Swaging

a punch and die for swaging this part. The work is located between the spring-operated holders *A* and directly over the die, which has a hole *B*, 3/32 inch deep, in it. The small end of ejector pin *C* forms the bottom of the hole in the die. When the piece is swaged into the die, this pin compresses

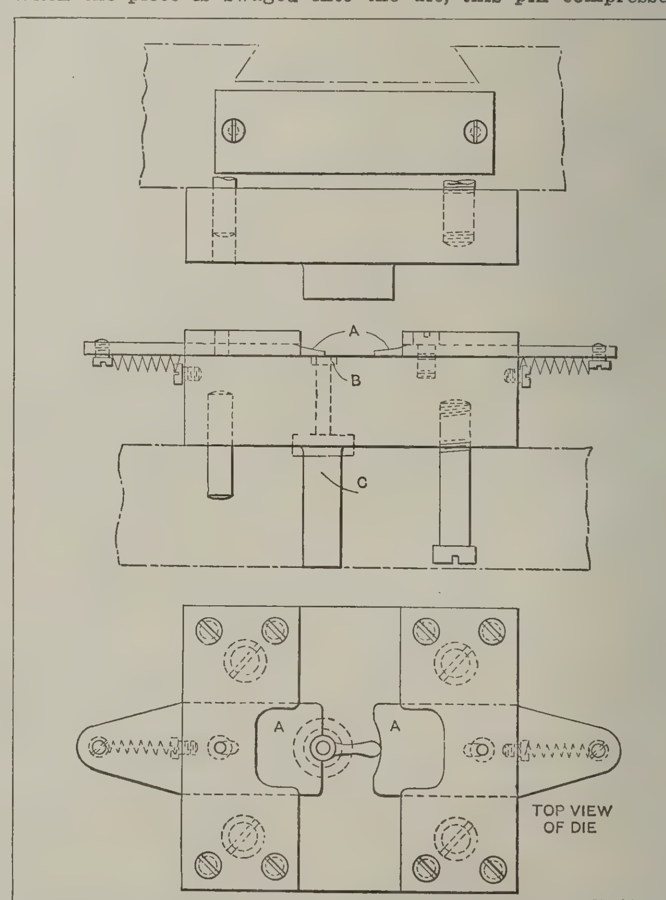

Fig. 2. Punch and Die for Swaging Operation

the rubber pad which is used for ejecting. A small ring is formed on the work by the hole through which this ejector slides; this is afterwards removed by a drilling and reaming operation through boss *D*, Fig. 1. BACON

MACHINING AN AUTOMOBILE SPIDER

The piece shown at *B* in Fig. 1 is known as an automobile spider. It has four arms which are finished on the outside, and a hole bored through the center. The machining operations on the spider are carried out as follows: In the first operation the spider is gripped in a three-jaw chuck, as shown in Fig. 1, one jaw being cut out to allow one of the arms of

the spider to set into it, thus furnishing a drive. While the hole through the spider is being bored and reamed with tools held in the turret, one side of the spider is faced with a back facer bar which is operated through the spindle, and the side next to the turret is faced with tools held on the cross-slide. In this operation the ends of the arms of the spider at *A* are also turned.

Before the second operation on this spider is done it is necessary to drill a small hole *A*, Fig. 2, which is used to locate the spider on the turret for the second operation. This hole is drilled in a jig as shown, which consists of a base on which the spider is set and an upper half which locates the

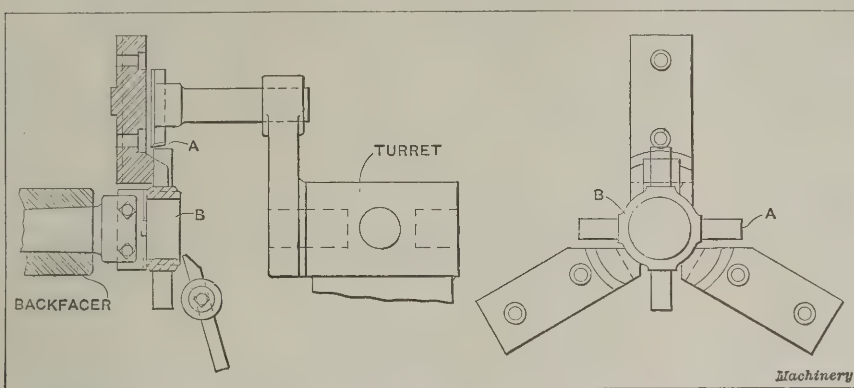

Fig. 1. First Operation—Turning, Boring and Facing

hole. Fig. 3 illustrates the method of machining the arms in the second operation, this being quite a departure from ordinary turret lathe practice, in that the tools are held in the headstock spindle, and the work on the turret. In place of the regular turret a special turret is used for holding the spiders, each spider being located in the same position as the preceding one by means of the hole mentioned above and the pin *A*, Fig. 3.

It is obvious that if there are four turret faces on the regular turret, the same will be true of the special turret, and each indexing of the turret brings another arm in line with the spindle, where it is operated upon. When the four arms are finished the machine is stopped and another spider put

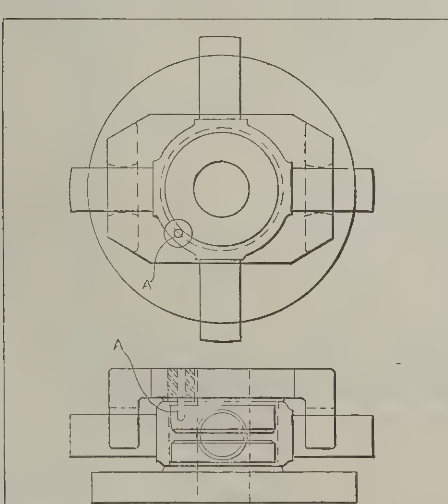

Fig. 2. Jig for Drilling Locating Hole

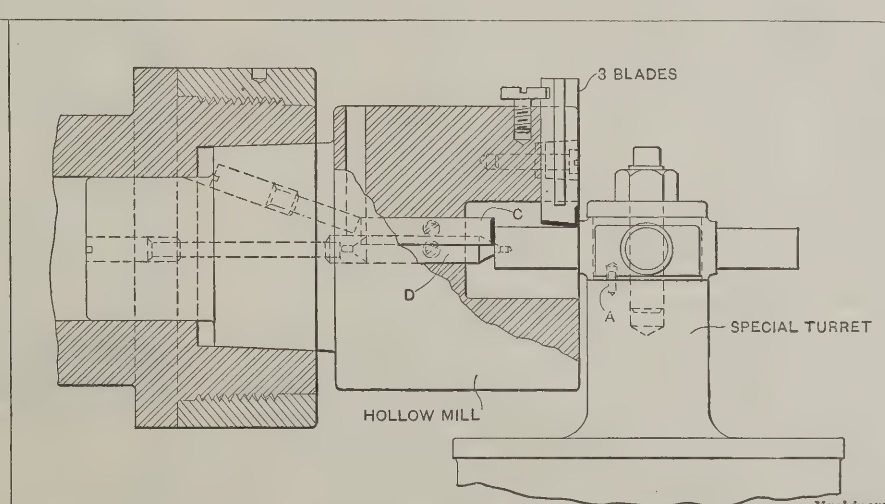

Fig. 3. Turning and Facing the Spider Arms

on. The machining on the arms of the spider is done with a hollow mill held in the spindle. In this mill there are three blades for turning, one facing blade *C*, which faces the end of the arms, and a small combination center-drill *D* which centers each arm. As the arms on the spider are opposite, they can be set between centers and ground, a pin being used to drive them by simply coming in contact with one of the arms not being ground; this saves the necessity of using a dog and is much quicker. F. Server

A COMPARISON OF SELLING METHODS

Some time ago we were in the market for a machine tool and wrote to two manufacturers who advertise in these columns. The selling methods of these two companies differed sufficiently to cause comment. Our letter asked for information regarding prices, the type of equipment that would be best suited to our requirements and the correct method of installation. The replies came promptly but the difference can be noted from the following: Firm No. 1 enclosed a blueprint photo of machine and a printed pamphlet of general information on the method of installation, etc. Their letter made no mention of the special information we asked for and appeared to be a stereotyped form. Nor was this information included in the pamphlet, and to complete a poor argument, the letter was signed in typewritten characters, no writer's name appearing. Firm No. 2 sent an attractive catalogue with prices—which, by the way, were higher than those submitted by firm No. 1—and a three page letter *fully* answering all of our requests, and calling attention to a few salient points not mentioned in the catalogue. They advised that their salesman would reach us within three days to enter into the matter still more fully. In conclusion, the letter was personally signed by the head of the firm, thus giving that touch of individuality which means so much. The salesman arrived on time, explained some minor points—the letter had covered nearly everything—closed the order, and the machine was shipped in three weeks. Although we would have paid for it on delivery, the builder insisted that we take up the thirty day trial offer, which was done. Needless to say, the machine is still in use and further purchases are now contemplated.

The reason for asking the special question concerning installation and equipment was that remodeling was necessary to accommodate the machine. It was necessary to start this work at once, in order to be ready when the machine arrived; consequently it was a matter of absolute necessity for us to have these questions answered. We notified firm No. 1 that the order had been placed, but received a stereotyped "follow up letter"—signed in typewritten characters as before. While merits, of course, were the final considerations governing our selection, the first impressions made by the letters went a long way in making the decision. It does seem as though some firms should adopt twentieth-century methods of selling their goods. One thing more; these firms were located in the same town and manufactured the same line of machines, so that both had equal opportunities of securing the business.

New Britain, Conn. J. M. Henry

PUBLISHING TECHNICAL INFORMATION

In the September issue of Machinery, appeared an editorial comment on an article recently published in *Canadian Machinery*. The article in question spoke of the selfishness of some engineers who refrained from giving out useful technical

information which was the result of personal research. Modern methods and ways of thinking are making this type of men a thing of the past.

There are, of course, various reasons for this policy, one of which was brought out by an experience which the writer recently had. The superintendent of a certain factory, having noted one of the writer's articles on a method of performing an important operation, came to him and said, "I don't believe in this sort of thing and the president also expresses himself as being against it." Upon being asked for the reason he replied, "Simply because we do not believe in the general education of the masses.". The writer refrained from making any comment, but to him it surely seems a narrow-minded view. The article did not reveal any trade secrets or information of that nature, being merely a description of a short cut in machine production.

Some people appreciate the publicity which comes from advertising, etc., but fail to appreciate the publicity value of giving out their methods of manufacture to the trade. Competition makes it necessary for every short cut to be applied, but does not, in the writer's opinion, require withholding information that would be helpful to a great many mechanics. This only refers to information that could be made public without loss to the works where the method originated.

It will generally be observed that the shops which guard their fancied secrets so jealously are the ones in which time, money and energy are wasted most freely. The reason for this is that their narrow-mindedness prevents them from accepting other known and tried methods of improving their working conditions. Perhaps they are ashamed of their methods. If this narrow view were broadened, it would clear away much of the mystery which surrounds the intelligent use of modern machine tools and appliances, and the benefits received would fully repay manufacturers for giving out information which is at their disposal. J. M. H.

DRAWINGS AND THE EYE-SIGHT

There is altogether too much unnecessary eye-strain among draftsmen that is weakening their sight. This is not brought on entirely by the continuous use of the eyes; other causes of eye-strain are making and reading drawings with lines of inadequate thickness, using lead pencils that are too hard, and making tracings from pencilings whose lines are barely distinguishable through the cloth.

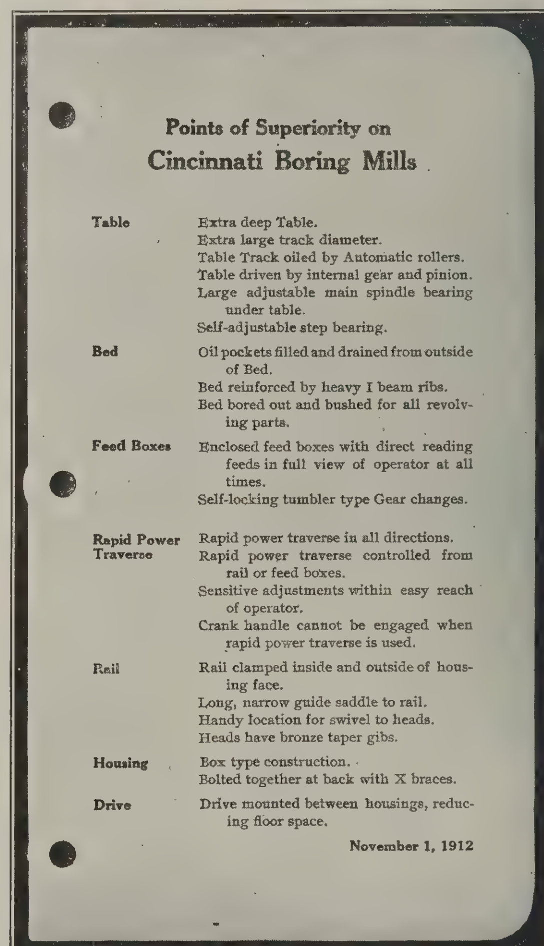
The exercise of a little discretion in selecting drawing materials and in drafting-room practice may be made the means of saving both the draftsmen and those who use their drawings from eye-strain. It is more difficult to trace a penciled drawing made on buff or cream colored paper than one made on white paper. Many draftsmen use but one degree of hardness in lead pencils—generally a 5–H or 6–H on all shades and grades of drawing paper. They do not appear to realize that there is a proper degree of hardness of lead for different papers, that will make a drawing "seeable" and "readable" through tracing cloth in all conditions of light, whether the day is stormy or bright. In most drafting-rooms, the papers used have a coarse-grained surface and are either white, buff or cream colored. Experience has shown that on white drawing paper, a 5–H pencil makes lines of sufficient weight, on the buff color a 4-H should be used, and on the deeper shades a 3–H is desirable. Since a much greater pressure can be secured in making lines with a lead pencil than with a pencil compass, the lead in the compass should always be one degree softer than the pencil. If this method is followed, all drawings will have good black lines, which will lessen the strain on the eyes, especially when making tracings.

Another means of relieving eye-strain is to make the light and shade lines thicker. The day of elaborate drawings for shop use has passed. Plainness and simplicity in drawings is both required and appreciated by workmen. It is better to use a drawing pencil having too blunt a point and make thick lines, than to use one filed down to a point like a needle. In making tracings, plenty of ink should be used. The lines that were formerly made for shade lines should now be the light lines, and the shade lines should be made just double the thickness. The lettering and figures on the drawing should be made with a coarse pen, and at least 5/16 inch high and 3/16 inch wide. Blueprints taken from such tracings are far more useful in the shop than many of the ones with sight destroying hair-lines, dwarfed letters and figures, and feeble looking arrow-heads that are now in use. All this may seem a radical change from the present method, but its general adoption would be a change in the right direction, as it would enable those with dimmed eyesight to read drawings more easily and prevent damage to the sight of those whose eyes are still good. JAMES E. COOLEY

Hartford, Conn.

PRICE SHEETS FOR SALESMEN

On page 235 of the November issue, engineering edition, attention is called to the loose-leaf price books that are now generally used by machinery salesmen. We have been sending out our price lists in this form for the past six years, the size of the sheet being 7¼ by 4 inches, suitable for the Morden No. 6 loose-leaf binder. All information which we issue for



Points of Superiority on
Cincinnati Boring Mills

Table	Extra deep Table. Extra large track diameter. Table Track oiled by Automatic rollers. Table driven by internal gear and pinion. Large adjustable main spindle bearing under table. Self-adjustable step bearing.
Bed	Oil pockets filled and drained from outside of Bed. Bed reinforced by heavy I beam ribs. Bed bored out and bushed for all revolving parts.
Feed Boxes	Enclosed feed boxes with direct reading feeds in full view of operator at all times. Self-locking tumbler type Gear changes.
Rapid Power Traverse	Rapid power traverse in all directions. Rapid power traverse controlled from rail or feed boxes. Sensitive adjustments within easy reach of operator. Crank handle cannot be engaged when rapid power traverse is used.
Rail	Rail clamped inside and outside of housing face. Long, narrow guide saddle to rail. Handy location for swivel to heads. Heads have bronze taper gibs.
Housing	Box type construction. Bolted together at back with X braces.
Drive	Drive mounted between housings, reducing floor space.

November 1, 1912

Morden Price List Sheet with Reinforced Holes

the use of salesmen, such as dimensions, talking points, motor information, etc., is printed on sheets of this size, and we have just adopted a scheme of reinforcing the holes as shown by the sample sheets enclosed. These price lists are referred to constantly by the salesmen, and unless some provision of this kind is made, the holes are soon torn through and new sheets must be supplied.

Cincinnati, Ohio CINCINNATI PLANER CO.

REFITTING A WORN STRAP ON AN ENGINE CONNECTING-ROD

The writer read with considerable interest an account in the August number of MACHINERY of how a number of rings that had been bored out too large were saved by shrinking and reboring them. This recalled to his mind a job of a somewhat similar nature which he saw done while an apprentice. A large engine was being repaired and generally overhauled. The strap for the connecting-rod required re-

fitting, but instead of making an entirely new strap, the old one was heated to a red heat across the end and immersed in cold water for about one-half the thickness of the stock; thus the outside portion contracted and compressed the inner portion in a manner similar to that explained in the article referred to. This method might be used to advantage in many cases, if it were better known.

Los Angeles, Cal. JOHN A. WOOD

EFFICIENCY OF WORM GEARING

We have read with much interest the article published in the September issue of MACHINERY entitled "Efficiency of Worm Gearing for Automobile Transmission." We have made a large number of tests on worm gearing in these works and our results do not confirm the results given in the article in question. We should be glad, therefore, to have certain points explained. The general trend of the tests given in Tables I to V shows that the efficiency decreases with decreasing load, which is entirely opposite to our results.

It appears to us that the loss in friction is proportional to the working pressure between the teeth, and, therefore, when the working pressure is less, the loss in friction is less. However, in Table III, "Second Speed" test, the loss at 36.95 H. P. is 0.84 H. P., and at 19.12 H. P., 1.14 H. P.; also, in the same table on the "Direct Speed" the loss at 49.35 H. P. is 1.21 H. P., and at 30.73 H. P., 1.89 H. P. We cannot see how these figures—and there are several similar cases in the other tables—can be substantiated.

We also note that later in the article appears the following remark: "The higher loads indicated were abnormal for the gears under consideration, and would not occur in any use to which the gears would normally be put." A consideration of the tables shows that as the highest efficiencies are always obtained at these abnormal loads the gear should surely be taken to be correctly rated for these loads, and a *smaller* and (according to these results) *more efficient* gear should be designed for the *normal* working load required. It also appears from the tables that if the load were still further increased, an efficiency of 100 per cent might readily be obtained.

In conclusion, we may say that our experience gives the following general results, *viz:* that the efficiency of a correctly designed gear increases considerably under light load and decreases under overload, and that the temperature rise of the oil is an exact measure of power loss in the gear.

Manchester, England. HENRY WALLWORK & CO., LTD.

I have read with much interest the comments made by Henry Wallwork & Co., Ltd., Manchester, England. In drawing the efficiency curves in Fig. 11 (September number) no attempt was made to smooth out the curves and so eliminate any inconsistencies which appeared. In the very nature of things it is impossible to obtain absolute accuracy in results where it is necessary to measure small differences of power, as in this case, especially when the speed of the instrument measuring input varies from that of the one measuring output.

I note that Henry Wallwork & Co. questions the decrease of the efficiency with decreasing load, and that their tests show entirely opposite results. It is certain that the friction of the gears does not vary directly with the tooth pressure. In other words, in wide variations of tooth pressure the friction does not vary widely. This being the case, the efficiency must increase with the load. Take an extreme case as an example: Assume that the friction does not vary at all, and is, in a given case, let us say, one horsepower. If, under these conditions the gear transmits two horsepower the efficiency would be 50 per cent. If the same gear transmitted 100 horsepower the efficiency would be 99 per cent. Of course, this is not intended to apply to any actual gear system, but is merely mentioned to illustrate the point that, in general, it should be expected that the efficiency would increase with the load until the breaking down point of the gear surface is reached.

In reference to the statement that the loads indicated were abnormal for the gears under consideration, this statement merely refers to the load to which the gears will be subjected when placed in an automobile transmission. It would be perfectly proper and normal to transmit the higher loads by means of these gears, but they are certainly in excess of what would occur in an automobile.

Providence, R. I. WILLIAM H. KENERSON

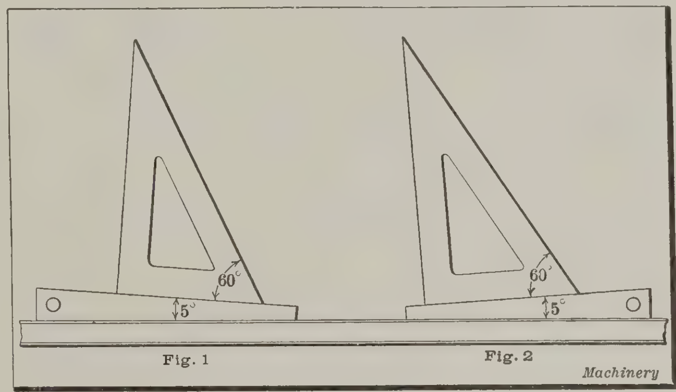
"DEVICE FOR DRAWING DOTTED LINES"

On page 215 of the November, 1912, issue of MACHINERY, engineering edition, I note an article entitled "Device for Drawing Dotted Lines." As the device referred to in said article is the subject of a patent granted to the writer (965,-945, dated August 2, 1910) please print this notice in the December issue to inform your readers accordingly, so that they may avoid infringement thereof. It is the intention of the writer, who is a patent attorney, to prosecute any form of infringement of said patent to the fullest extent.

13-21 Park Row, New York BENJAMIN ROMAN

SUPPLEMENTARY ANGLE FOR DRAFTSMEN

The supplementary angle shown beneath the triangles in the accompanying illustration consists of a piece of celluloid with two of its sides or edges at an angle of five degrees to each other. With one of these angles, and the regular 45 or 30—60-degree triangles, all angles at intervals of five degrees from 0 to 360 degrees can be drawn. Fig. 1 shows the 60-degree angle combined with a 5-degree angle in such a way as to make it possible to draw an angle of 65 degrees. In



Method of using the Supplementary Five-degree Angle

Fig. 2 the 5-degree angle is reversed, making it possible to draw an angle of 55 degrees. DRAFTING ROOM

[A device of a somewhat similar nature has been invented and patented by James Dangerfield, and was described in the August, 1903, number of MACHINERY. The difference between the device here mentioned and that of Mr. Dangerfield's is that the latter consists of a set of ten angles from 1 to 10 degrees. This makes it possible to obtain accurately every whole-degree angle from 0 to 360 degrees. Sets are also made with two additional ¼- and ½-degree angles, making them practically as universal as the regular draftsman's protractor. —EDITOR.]

DRILLING HOLES IN GLASS

Occasionally we are called upon to do small jobs of drilling holes in glass. The common method known to the writer is a long and tedious process, *viz:* placing a short piece of brass tubing the diameter of the hole desired in the drill chuck and grinding the hole through the glass with powdered emery and oil. A more effective and simpler way is to take a rat-tail file about the size of the hole to be drilled and break it at about the middle so that while drilling it will not wedge the hole. Place the tang end of the file in the drill press chuck and run at high speed. Place the glass under the rapidly revolving file and let the file come gently in contact with the glass by moving the handle up and down. For a lubricant use turpentine. In this way holes are drilled in one-fourth the time required by the old method.

Chicago, Ill. O. M. HANCE

HOW AND WHY

DEPARTMENT INTENDED TO CONTAIN CORRECT ANSWERS TO PRACTICAL QUESTIONS OF GENERAL INTEREST

Give details in full and name and address. The name and address will not be published with the answer.

ACTION OF BELTS WHEN THE SHAFTS ARE OUT OF PARALLEL

The answer in the October number to the inquiry regarding the action of belts on pulleys is correct in part only. The crowning of the pulley faces causes the belt to run to the "high side," that is, crowd to the center where the diameters are largest, as you state. But when the shafts are out of parallel the belt runs to the "low side," and if the shafts are badly out, the belt will run off from the low side. In other words, a high side made with a "monkeywrench" (shafts out of parallel) does not act like a crowned face. I have had many years' experience with pulleys and belts and have never known them to act in the contrary way, as described in your answer.

Amherst, Nova Scotia B. G. Cox

DIES FOR NAIL-MAKING MACHINERY

G. W. E.—I would like to obtain information on the making and tempering of dies used in nail-making machinery. At present we have to anneal, redress and temper the dies whenever they become worn, having for this purpose a gas stove with pyrometer for hardening and an oil bath with thermometers for tempering. We feel, however, that our practice is defective in comparison with that of some American firms, who we believe, regrind the cutters several times without drawing the temper. We have tried grinding the vees inside to about a fifty-degree angle, but encountered the difficulty that carborundum wheels will not keep the necessary sharp edge. Apparently it would be necessary to use a steel disk studded with diamond dust to secure the desired result by grinding.

A.—The subject is of sufficient importance to make a full reply from any reader having had general experience on the maintenance of nail-making machinery, of general interest. We will be glad to receive contributions on the subject.

STRAIGHT FACE VS. CROWN FACE IDLER PULLEYS

W. M. F.—Are idler pulleys which run on the outside of opposite side of the belts on transmission pulleys usually made with straight or crown face—and why?

A.—Practice differs. The H. W. Caldwell & Son Co. furnishes straight face pulleys for idlers. The reason given is that the driving and driven pulleys having crown faces, of course, the belt is kept in the center of these pulleys by the crowning. If the intermediate idler pulleys are also made with a crown face, and if the crown is not exactly in line with the crown of the driving and driven pulleys, there will be an objectionable moving back and forth of the belt. The Dodge Mfg. Co. makes idler pulleys both crown and straight face, depending upon the condition, but the greater part of its product is made with the crown face, and crown face pulleys are furnished when not otherwise specified. The reason given for preferring the crown face idler pulley is that it is often necessary to "lead" the belt slightly and a crown face idler assists in doing this. No objection, however, is offered to the straight face idler, and either type is furnished when specified.

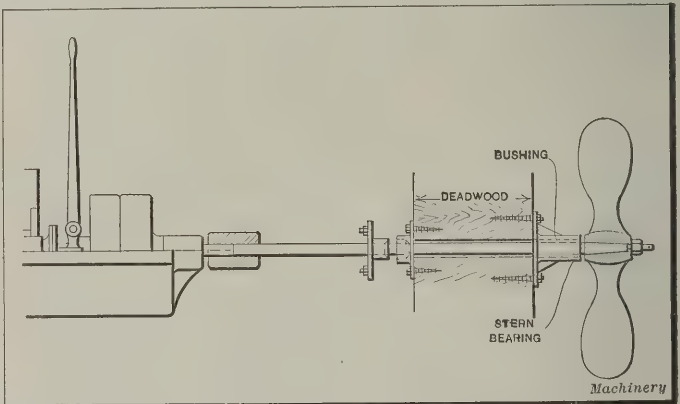
TOOLING FOR INTERCHANGEABLE MANUFACTURE

A. L. B. Co.—The question has arisen in our factory as to whether or not it is necessary to build a model machine to construct the tools, jigs and fixtures for same, provided the machine is known to be practically correct from a manufacturing standpoint, but not mathematically correct in all its parts. The machines were originally built without drawings and little by little were improved until we have a practically standard machine. About two years ago one was disassembled and drawings of the parts made, no assembly of the machine having been made or any methods used to check the accuracy of the parts. We attempted to use these drawings in conjunction with parts of the machine in making jigs and fixtures, but found that it was not feasible to proceed in this manner because of variations in dimensions of parts. The question is, how should we proceed? Do you think it necessary to build a sample machine first to check the drawings for accuracy and then make the tools and jigs to manufacture the parts?

A.—The exact procedure in tooling for manufacturing is something on which probably there would be no general agreement among toolmakers and manufacturing experts who were given the problem to solve. It would depend very largely on the type of machine, size of parts and the degree of accuracy required. In general, we would say that the handmade machine should be disassembled and accurate drawings made of every part. No changes whatever should be made in dimensions or shapes except in those parts immaterial to the working of the machine. Having made the drawings, jigs should be made for each part using the part to get the shape, distance between holes, etc. Where great accuracy of related parts is required, and trouble in the functioning of the machine is anticipated, the jigs for the parts should be made simultaneously, and changes made if required to secure closer adjustments. Having proved the dimensions and shapes of these parts satisfactory, the drawings should be changed and corrected when necessary to agree. The work should be laid out so that the machine can be assembled, and each part checked by the pieces produced in the jigs. When the work has proceeded to the finished stage, a complete manufactured machine will have been produced from the jigs, each jig having been proved as the work proceeded. It cannot be said that this procedure would invariably result in an absolutely perfect machine, but the probabilities are that the change required would be of an insignificant character, not expensive to make. Suggestions from readers who have had experience in tooling for interchangeable manufacturing are invited.

HOW TO FIX A BUSHING ON A PROPELLER SHAFT

S. H. S.—Will you kindly advise me if there are any effective methods of fixing bushings on propeller shafts where they bear in the stern bearing of a boat? The illustration shows the manner of installation. The shafts are tobin bronze and the bushings are bronze, being from ¼ inch to ⅜ inch thick, 8 inches long on a 2½-inch diameter shaft. I have shrunk and pinned the bushings on and have sweated them on, but they all work loose sooner or later. The bushings run in lignum vitæ lined bearings or bronze bearings.



The reason I have deduced for the peculiar loosening up of the bushings is that, being under water, more or less sand and dirt get into the stern bearing and quickly wear it so as to let the shaft pound or hammer, which causes the bushing to stretch and loosen on the shaft. The harder and thicker the bushings are made, the longer they last, but all of them loosen if used long enough.

A.—The oxy-acetylene process might be used to secure a sectional bushing which could be applied as a series of narrow rings and successively welded to the shaft. This method is slow and rather expensive and perhaps the readers can suggest simpler and more effective methods.

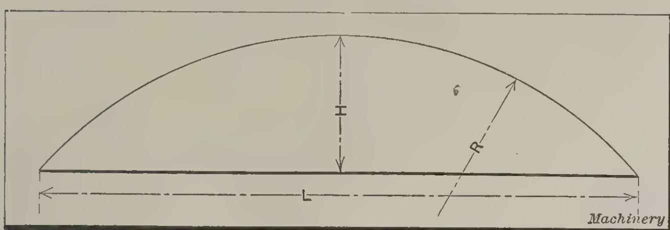
TO FIND RADIUS OF ARC WHEN LENGTH OF CHORD AND HEIGHT OF ARC ARE GIVEN

J. E. H.—Kindly give me a formula for finding the radius of a circular arc when the length of the chord and the height of the arc or segment of the circle are given, as indicated in the accompanying illustration.

A.—A formula for obtaining the radius of a segment, when the data mentioned above are given, was published in MACHINERY in November, 1906; this formula may also be found in the engineering handbooks. If L is the length of the chord; H the height of the arc; and R the radius to be found, then:

$$R = \frac{\frac{(\frac{1}{2} L)^2}{H} + H}{2}$$

This formula looks rather cumbersome and could be some-



what simplified so as to take the form:

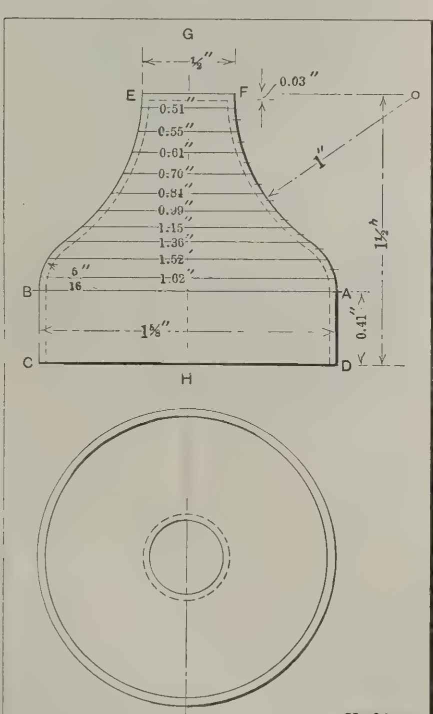
$$R = \frac{(\frac{1}{2} L)^2 + H^2}{2H}$$

The second form of the formula, however, requires more numerical calculation than does the first, which, therefore, is preferable.

TO FIND THE AREA OF A SURFACE OF REVOLUTION

R. B. H.—I would like to see a formula published for finding the outside area of sheet metal cups. An example of the kind of cups referred to is shown in the accompanying illustration.

A.—No general formula can be given for obtaining the area of a symmetrical body of the form shown in the illustration. However, the approximate area can be found by a comparatively simple method. In the illustration, the dimensions written in common fractions are the given dimensions. Those written in decimals are found by actual measurement on a figure drawn to scale. The method of finding the area is as follows: First separate such areas as are cylindrical, conical or spherical, as these can be found directly by exact formulas found in all engineering handbooks. In the example shown, $ABCD$ is a cylinder, the area of the surface of which can be easily found. The top area EF is simply a circular area, and can thus be computed separately. The remainder of the surface generated by rotating line AF about the axis GH is found by the approximate method to be explained. From point A, set off equal distances on line AF. In the present case each division indicated is ⅛ inch long. From the central or middle point of each of these parts draw a line at right angles to the axis of rotation GH, measure the length of these lines or diameters (the length of each is given in decimals), add all these lengths together and multiply the sum by the length of one division set off on line AF (in this case, ⅛ inch), and multiply this product by π. This gives the approximate area of the surface of revolution.



In setting off divisions ⅛ inch long along line AF, the last division does not reach exactly to point F, but only to a point 0.03 inch below it. The part 0.03 inch high at the top of the cup can be considered as a cylinder of ½ inch diameter and 0.03 inch height, the area of the cylindrical surface of which is easily computed. By adding the various surfaces together we get the total surface of the cup as below:

Cylinder, 1⅝ inch diameter, 0.41 inch high,	2.093 square inches
Circle, ½ inch diameter,	0.196 square inches
Cylinder, ½ inch diameter, 0.03 inch high,	0.047 square inches
Irregular surface,	3.868 square inches
Total,	6.204 square inches

The method used in finding the area of the irregular shaped part of the cup is based on the Pappus or Guldinus rule, which states that the area of a surface generated by the revolution of a line about a central axis equals the length of the line, multiplied by the path of its center of gravity, the line being considered as a fine wire. As it is a matter of considerable difficulty to find the center of gravity of an irregularly curved wire, the simplest way in which this method can be applied is to divide the irregular shaped line into a number of parts, each one of which can be considered as a straight line, having its center of gravity at the middle of the line. In this way we find the area of each one of the divisions by multiplying the length of the division by the circumference of the circle which passes through its center of gravity. As all the divisions, in our case, were made of equal length, the simplest method was to add the lengths of all the diameters of these circles together, and then multiply by π and by the length of each division, ⅛ inch.

In testing out the accuracy of this method, the surface of a half-sphere 6 inches in diameter was found by dividing a great circle into parts ¼ inch long and finding the area by this graphical method. The exact area of this half-sphere is 56.55 square inches. The graphical method, using only an ordinary draftsman's scale, compass and triangle, gave an area of 55.28 square inches, which may be considered fairly accurate for an approximate method. The half-sphere was selected for the test case because it presents one of the difficult shapes for the application of this method, as the curved outline merges from a vertical into a horizontal direction; the surface being convex throughout, the errors are also likely to be all in one direction. A more accurate result may be expected when part of the surface is convex and part concave.

NEW ALUMINUM REDUCTION PLANT

The General Electric Co., Schenectady, N. Y., is building seven vertical water wheel type direct-current electric generators for the new plant of the Southern Aluminum Co., at Whitney, N. C. Each machine will have a rating of 5000 K. W., delivering 20,000 amperes at 250 volts at a speed of 170 R. P. M. They will be the largest direct-current machines built. Two similar direct-current generators of the same type rated at 2500 K. W. and two 1250 K. V. A. alternators will be also installed. The Southern Aluminum Co. is capitalized at $8,000,000 and will become an important factor in the production of aluminum. The plant will be in operation about the middle of 1914, and will rank among the greatest and best equipped for the manufacture of aluminum in the United States. In the complement of buildings are nine furnace rooms, wherein the aluminum will undergo the various processes incident to conversion into aluminum. Each of these structures measures 60 by 500 feet and one electrode factory of similar dimensions is also included in the group. Aluminum, because of its lightness and toughness, is becoming of more and more importance in many lines of industry. Aluminum wire and cable are displacing copper for the transmission of high tension electric energy. It is made from a clay known as bauxite, found extensively in Georgia and the Middle West. The Southern Aluminum Co. will treat only alumina which has been made from bauxite. The engineering work is in charge of Dr. Paul Heroult, a prominent French engineer.

NEW MACHINERY AND TOOLS

THE COMPLETE MONTHLY RECORD OF NEW DESIGNS AND IMPROVEMENTS IN AMERICAN METAL-WORKING MACHINERY AND TOOLS

AMERICAN HIGH-SPEED SENSITIVE RADIAL DRILL

The American Tool Works Co., Cincinnati, Ohio, has added to its line the high-speed sensitive radial drill illustrated herewith. This machine is designed for drilling and tapping small holes at high speed. It is said to combine the high-speed efficiency of the plain sensitive drill with the productive capacity of the radial drill. Convenience in operating a machine of this type is an essential feature, as the actual time consumed in drilling a hole is often very small as compared with the time which elapses before the machine is set to drill the next hole. The importance of this consideration has been kept in mind in designing the present machine, and all levers and other operating members have been conveniently located for the workman, in order to simplify the operation of the machine as much as possible.

The feed lever is located on the head within easy reach of the workman's right hand, affording a convenient means of operation and obviating any possibility of interference with the work set up on the table. Another advantage of the ratchet lever feed used on the American sensitive radial drill lies in the fact that the lever is automatically disengaged from the rack pinion shaft when it is placed in its vertical position, so that the spindle can be quickly adjusted up and down by means of a small star knob on the end of the rack pinion shaft. This affords a rapid and convenient method of bringing the drill to and from the work.

The head is accurately balanced and can be moved rapidly along the arm by means of a rack and pinion operated by a handwheel. This handwheel is located on the front of the head on the operator's left-hand side, enabling him to swing the arm with his right hand and at the same time adjust the head along the arm with his left hand. The arm binding lever is located on the column end of the arm, where it is always within easy reach of the operator. The head is of very simple design, consisting of a main saddle which has a bearing on the arm and carries an auxiliary head upon a vertical dovetail. The sliding head is so arranged that it can be moved to or from the table, thus affording accommodation for quite a wide range of work. The auxiliary head can be securely clamped at any point along the dovetail by means of a lever conveniently located on the front of the saddle, while the head proper can be firmly bound to the arm by a lever on the back of the saddle which is within easy reach of the operator when he stands at the front of the machine.

In the elevating table type of machine shown in Fig. 1, the table is of semi-box construction, affording a large working surface. It has a bearing of ample width on the face of the column which insures a high degree of rigidity, and is equipped with a gib adjustment and two binders for locking it securely in position. The vertical movement of the table is accomplished from the front by means of a crank which imparts motion to the elevating screw through a pair of miter gears located under the table. The arm is of the American parabolic beam and tube section which has proved itself to be exceptionally rigid on the larger sizes of radial drills. Its construction is such that the lower line is parallel with the table, thus enabling the full capacity of the drill to be utilized at any point along the arm. It swings easily on the column and may be securely clamped in any position by means of a convenient binding lever. The arm does not move vertically; therefore provision is made on the head for variable heights of work.

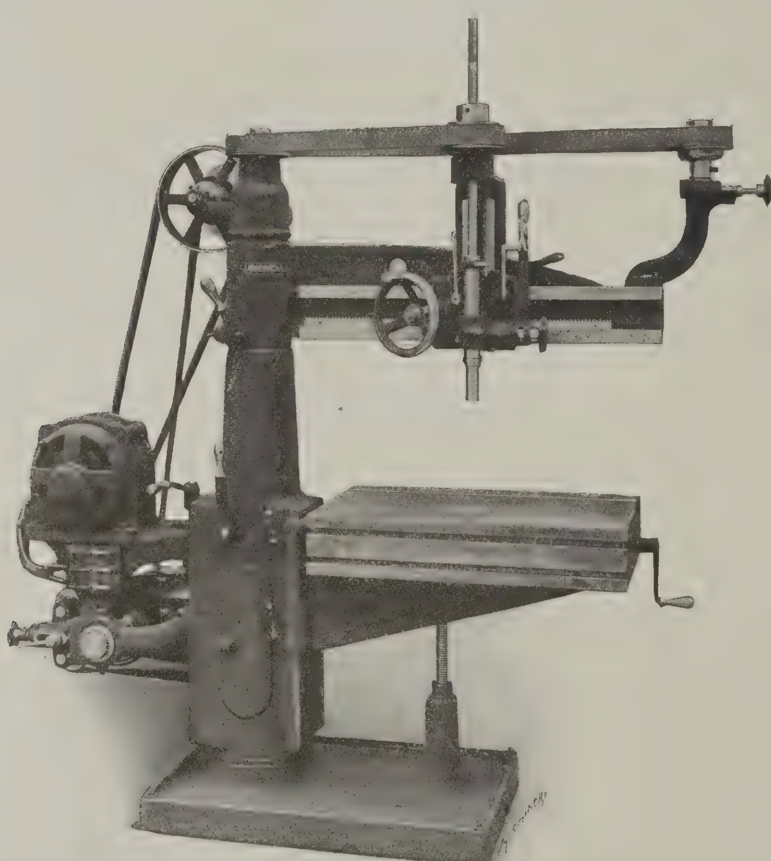

Fig. 1. Motor-driven Radial Drill equipped with Elevating Table and Tapping Attachment

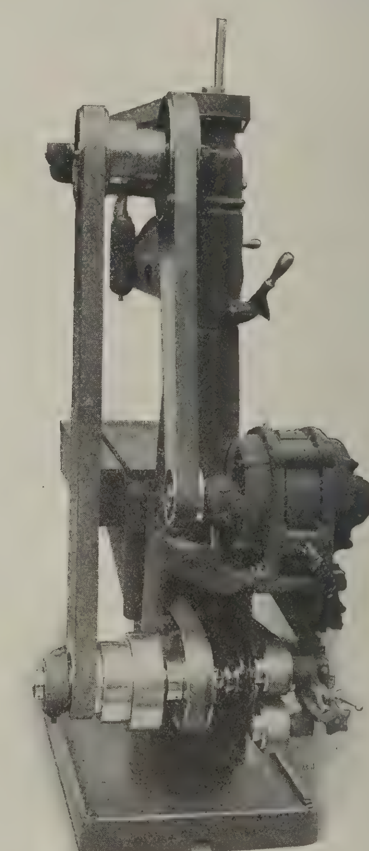

Fig. 2. Arrangement of the Drive

There are no gears in the driving mechanism of this drill from the countershaft to the main spindle, the drive being effected by means of a two-inch double belt running at high speed. This drive transmits an abundance of power directly to the spindle of the drill, the spindle belt being kept at the proper tension by turning the star knob located on the arm bracket. All of the driving and idler pulleys are equipped with special ball bearings which consist of a double set of hardened and ground ball races and cones; one set is located at each end of the pulley journals. These bearings are so

constructed that they are dustproof and form a retainer for the lubricant; vaseline or graphite is preferable for this purpose and need only be renewed at long intervals. The countershaft is especially designed for high-speed work and provides for two speeds. The hanger boxes are of an improved gravity and wick oiling type, taking their supply from large oil reservoirs and only needing attention at long intervals. The countershaft carries a three-step cone pulley with a pair of friction pulleys 10 inches in diameter and 3 inches face, and should run at 310 and 387 R. P. M.

This machine may be equipped with a tapping attachment, and with belt-driven machines so equipped a single-speed countershaft is furnished with six spindle speeds which are obtained through a three-step cone pulley and a pair of friction pulleys of different diameters located on the rear of the machine.

The spindle is of high-carbon crucible steel, accurately ground and provided with a dustproof self-lubricating ball thrust bearing. It has six changes of speed ranging from 300 to 900 R. P. M. in geometric progression, and is provided on the top with an adjustable stop-collar which may be used as a depth gage. The column is of tubular section, ribbed internally to provide the necessary rigidity. In addition to the type of machine illustrated, this radial drill is built with a stationary table, or with a pedestal base which makes it especially suited for large sizes of work. The regular equipment includes a countershaft and belts, no wrenches being required. All of the motor-driven machines are regularly equipped with a tapping attachment.

BILLINGS & SPENCER SAFETY LATHE DOG

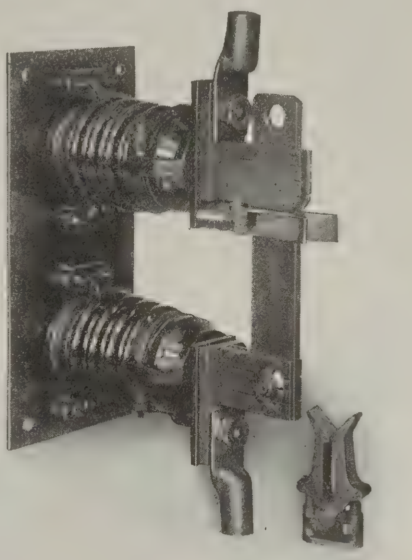
The safety lathe dog illustrated herewith is the product of the Billings & Spencer Co., Hartford, Conn. This form of dog embodies the simplicity, strength and convenience of the ordinary dog with the additional advantage of safety. The essential parts are the same as the design which is universally used, including the regular square head, so that no special tool is required for adjustment. The guard consists of a cover for the screw which is easily manipulated, being merely pushed to one side when it is required to uncover the screw head. The guard is then sprung back into position forming perfect protection for the operator. This dog has been thoroughly tested in the manufacturers' shops and has proved efficient under all conditions.

Billings & Spencer Safety Lathe Dog

LOCKING DEVICE FOR ELECTRIC SWITCHES

The locking device for electric switches here illustrated has recently been developed by the General Electric Co., Schenectady, N. Y., to eliminate the delays which are frequently caused by having machinery shut down through interruption of the power service. This device prevents the blade of a disconnecting switch from opening except where it is intentionally pulled by the operator. Instances are on record where the blades of a disconnecting switch, not protected by this device, have been thrown open or partially open by magnetic repulsion and destroyed when a short circuit has occurred on the line. In such a case, the destruction of the switch means that the circuit will be put out of commission while a new switch is being installed, unless there are duplicate circuits.

This safety locking device is a unit in itself and can be easily applied to any G. E. type L, Form G6 switch by merely clamping it to a support placed between the clip block and the insulator cap. It is designed to be operated with a switch hook and consists essentially of two brass bell cranks, hinged together at the ends of two shorter arms and held closed by compression springs. The projections or jaws in the outer ends of the two longer arms close in front of the blade, thus preventing the latter from coming out of the clips. Each bell crank is provided with a dog which moves in a slot in the bell crank elbow, the dog being hinged at this point. Two compression springs, one pressing outward from the switch base against the elbow of each crank and also against the dog, keep the bell cranks closed and the dogs pressed against the back of the switch blades.



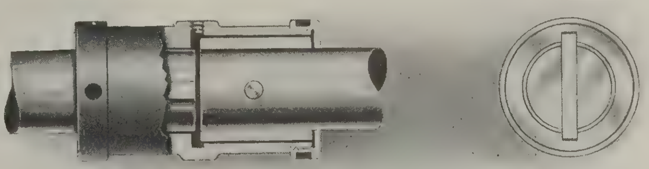
Locking Device to prevent Electric Switches from being accidentally opened

To open the switch, the outer ends of the bell crank are pressed back away from the blades, allowing the dogs to come forward and rest upon the sides of the blades; in this position they hold the jaws apart in front of the blade and allow the switch to be opened. Withdrawing the blade of the switch from between the dogs causes the jaws to automatically close against the sides of the blades and to snap shut as soon as the blade is completely withdrawn. As the outer edges of the jaws are beveled, the switch blade can be readily pressed back to the closed position between the clips, when the jaws close automatically in front of the blade, locking the latter in the closed position. The operator cannot forget to lock the switch closed because it automatically locks itself. This device is made in standard sizes to fit 300, 600, 800 and 1200 ampere switches, and can also be furnished for a switch of any other capacity.

MC EWEN IMPROVED STEEL COUPLING

A new form of flexible coupling, constructed entirely of crucible steel, has recently been introduced by McEwen Bros., Wellsville, N. Y. It is known as the McEwen coupling, and being small and consequently light in weight, it is particularly suited for classes of service in which it is necessary to reduce inertia as far as possible.

The keys extend right through the shafts and are set at right angles; provision is made to take care of a reasonable amount of non-alignment, but the ample key bearing surface and exceptionally good lubrication does away with any noise or tendency towards serious wear. This type of coupling was first used on McEwen Bros.' pumps, direct-connected to steam turbines, where it was kept in continuous service for several months at a time. The ability of the coupling to stand up under such a severe test appears to demonstrate its fitness for a variety of classes of service; such as reversible motor drive for machine tools, blowers, rotary pumps, and a variety



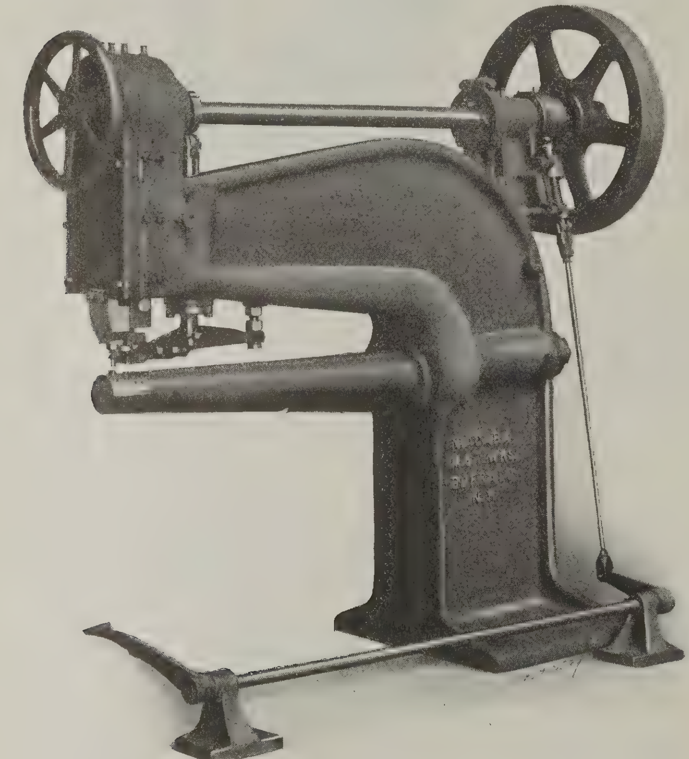
McEwen Improved Steel Coupling

of other cases where high speeds make the conditions of service particularly trying.

NIAGARA PUNCHING AND RIVETING PRESS

The Niagara Machine & Tool Works, Buffalo, N. Y., has recently added to its line the punching and riveting press illustrated below. This machine is designed to handle punching and riveting work in the manufacture of pipe, culverts, etc. Two thicknesses of material are punched and, at the same time, a rivet put in the hole punched on the previous stroke is headed, the rivet being inserted with the head upward. This method of combining riveting and punching in one operation, saves time, but is only applicable when the rivets are uniformly spaced. The distance between rivets can be varied from 1 5/16 to 2 3/4 inches.

The rivet header and punch are mounted in adjustable holders fastened to separate slides; these slides are actuated



Niagara Punching and Riveting Press

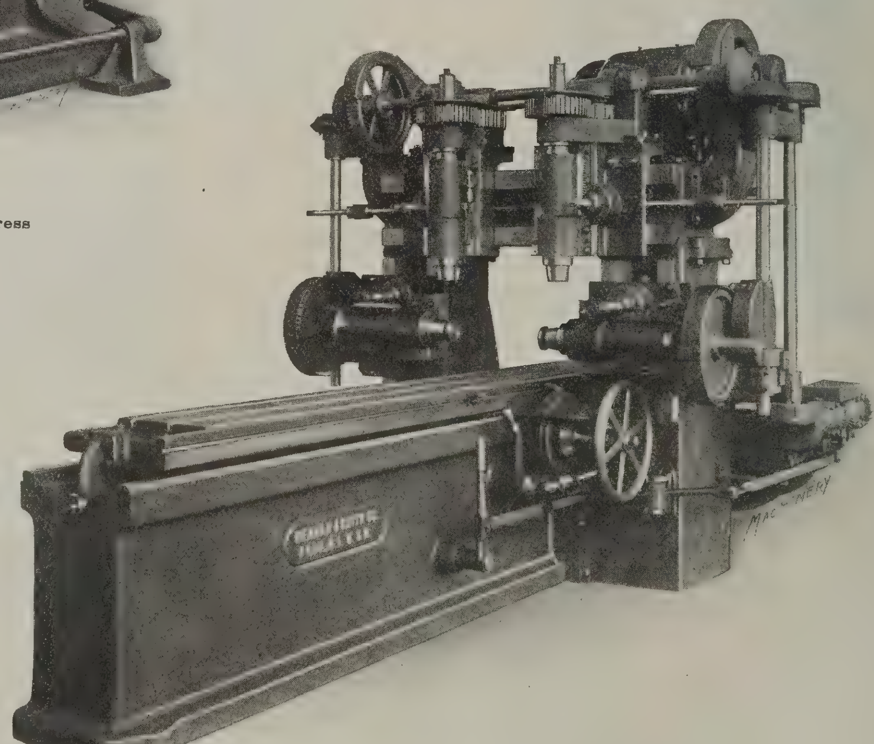
by two eccentrics and pitmans from the main shaft. It is also possible to use this machine entirely for punching holes or for riveting, or it may be used for punching and riveting alternately. When it is desired to use the machine entirely for riveting, the operator can quickly put the punch out of operation by means of a gag. When it is desired to punch without riveting, the rivet punch will run idle. The stripper or hold-down, which is actuated by a cam, clinches the material while it is being operated upon, and then strips the stock from the punch on the up stroke. The press is provided with an automatic jaw clutch and the motion of the slides can be started either by means of a hand-lever or a foot treadle. When the lever and treadle are released, the slides stop automatically at the top of the upward stroke. The machine has a throat 36 inches deep and the horn is a steel forging 5 inches in diameter at the outer end and 7 inches in diameter at the inner end. The press will upset a rivet cold up to ¼ inch in diameter, and will punch a hole ⅜ inch in diameter through ¼-inch iron or its equivalent. The gross weight of the machine is about 3600 pounds.

BEAMAN & SMITH FOUR-SPINDLE MILLING MACHINE

The four-spindle milling machine illustrated herewith is a recent design built by the Beaman & Smith Co., Providence, R. I. Reference to the illustration will show that there are two horizontal and two vertical spindles, the former having a vertical movement on the uprights and the latter a horizontal movement on the cross-rail. The table has a working surface 17 inches wide by 10 feet long; it has three T-slots finished from the solid metal and two rows of holes for stop-pins. The movement of the table on the bed is 10 feet 9 inches, and it is provided with a power traverse of 10 feet per minute in either direction. The automatic stop and feeds are arranged to maintain the desired rate at any spindle speed, which is a very important feature, as the rate of feed determines the quantity of work produced. The table is operated by a screw revolving in a bronze nut, the thrust being taken by ball bearings. Positive feeds for the table are provided by means of a geared feed-box which is conveniently located, and the change from one rate to another can be quickly obtained. There are nine changes ranging from 1 inch to 12.3 inches per minute at a driving-shaft speed of 500 R. P. M.

The spindles are of crucible steel and run in boxes of hardened bronze. They have a 6-inch independent adjustment and the ends are tapered to 3¼ inches in diameter for face milling cutters; No. 12 Brown & Sharpe taper holes are provided for cutter shanks and arbors. Each spindle has a hole through its center for the retaining bolt. The front bearings are 3⅞ inches in diameter by 5 inches in length, and are provided with means to compensate for wear. The rear bearings are 2¾ inches in diameter by 4¾ inches in length. All of the spindles are driven in unison. The gearing for the vertical spindles has a ratio of 7¾ to 1 and gives a spindle speed of 66 R. P. M. For the horizontal spindles, the gearing ratio is 21¾ to 1 and gives a speed of 23 R. P. M.

The machine is driven by a variable speed, 10-horsepower motor, geared to the driving shaft in the ratio of 3 to 1; the motor speed ranges from 500 to 1500 R. P. M. This machine



Beaman & Smith Four-spindle Milling Machine

can also be arranged to be driven by a 5-inch belt on a three-section cone with steps ranging from 11½ to 16 inches in diameter. When belt driven, the countershaft has tight and loose pulleys 14 inches in diameter and runs at 360 R. P. M.

The construction of the machine is in accordance with the latest practice. The quick running shafts are mounted in

bronze lined boxes; the bearings are finished by grinding; all sliding surfaces are scraped to an accurate fit; all gears are cut from the solid, the bevel gears being made by the Bilgram process; and many of the gears are of steel. The distance between the uprights is 30 inches; and from the ends of the vertical spindles to the top of the table, the least distance is 9 inches and the greatest distance, 15 inches; the least distance between centers is 10⅝ inches and the greatest distance, 30 inches. From the center of the horizontal spindles to the center of the table, the least distance is 4 inches and the greatest distance, 10 inches; between the ends, the least distance is 6 inches and the greatest distance, 18 inches. The weight of the machine is approximately 20,000 pounds.

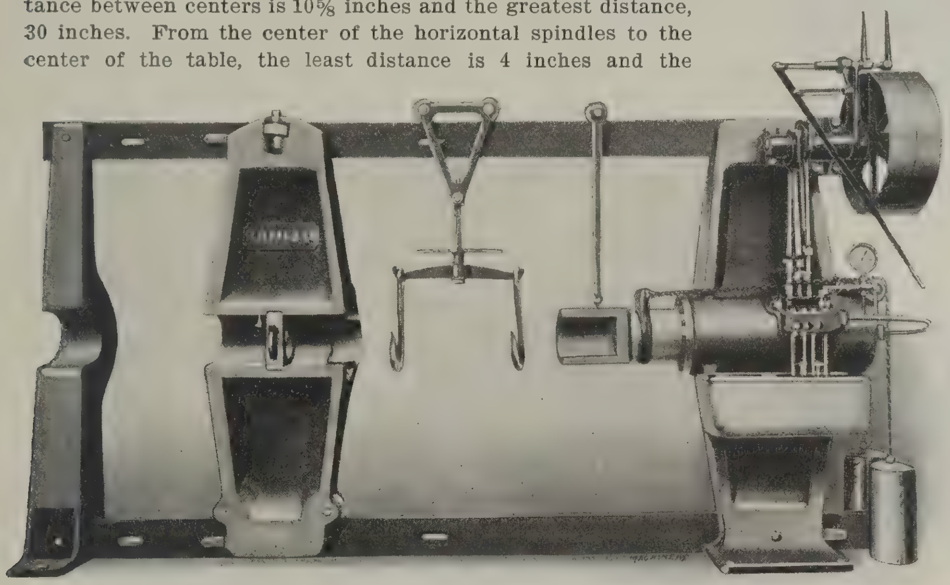


Fig. 1. Press for forcing Railway-car Wheels on and off Axles

THREE HYDRAULIC PRESSES

The Hydraulic Press Mfg. Co., 84 Lincoln Ave., Mt. Gilead, Ohio, has recently placed upon the market three hydraulic presses which are illustrated in Figs. 1, 2 and 3. The press shown in Fig. 1 is designed for forcing railway-car wheels on and off the axles, and delivers a firm steady pressure that will seat the wheel securely. Strength in all parts is obtained by the use of steel instead of iron or semi-steel. The steel cylinder is much lighter than when made of cheaper material, and is also far more dependable in service. Pressures up to 2500 pounds per square inch are available, and this is quite sufficient for the work done by this machine.

The ram has a long bearing in the cylinder which insures freedom from binding. As soon as the pressure is released, the ram is drawn back by weights and chains, and in order to enable it to withstand heavy pressure, the ram is faced with a hardened steel bearing. The resistance head is provided with a throat which serves the double purpose of a guide and stop. The parallel bars are slotted and provided with keys for shifting the resistance head to the right distance from the ram. This resistance head, in addition to the adjustable lifting hooks and hollow pressure block, shifts on the parallel bars by means of rollers. The press is operated by a motor drive or by a power attachment, with tight and loose pulleys for operating with a belt. It is equipped with from one to four pump plungers which can be arranged to drive the ram at any desired speed. The bronze pump flanges are driven by eccentrics and knockout attachments control the speed of the pump without stopping it.

The portable inverted press illustrated in Fig. 2 was built for the U. S. Government for forcing and general purposes; it is to be used at the Purdue University Experiment Station. One of its striking features is the unobstructed daylight space which makes it possible to place the press in contact with all sizes of machinery. By simply boring a hole in the platen, the press can be used for forcing wheels on and off shafts. The ram is returned by a rack and pinion which is placed back of the cylinder to be out of the way. The parts of the press taking stress are constructed of steel, the cylinder being made separate from the beam. The wheels have roller bearings which make the movement of the press from place to place an easy matter. The pump is small and compact, having a ⅝ inch piston with a 3½-inch stroke; the piston guide is made in one piece and serves the double purpose of guide and fulcrum for the pump handle. A safety valve in connection with the pump protects the frame against overload.

Fig. 3 illustrates a forming press which could also be applied to a variety of general classes of heavy work. The press is entirely above the floor line and can be easily installed. The speed of the ram in starting is increased by placing two pumps on the press. The platen, pressure head and strain rods are of steel, and are designed to withstand the great stress to which they are subjected in operation. A maximum stress of one hundred tons will seldom be exceeded in the general run of work, but a safety valve and pressure gage are provided to

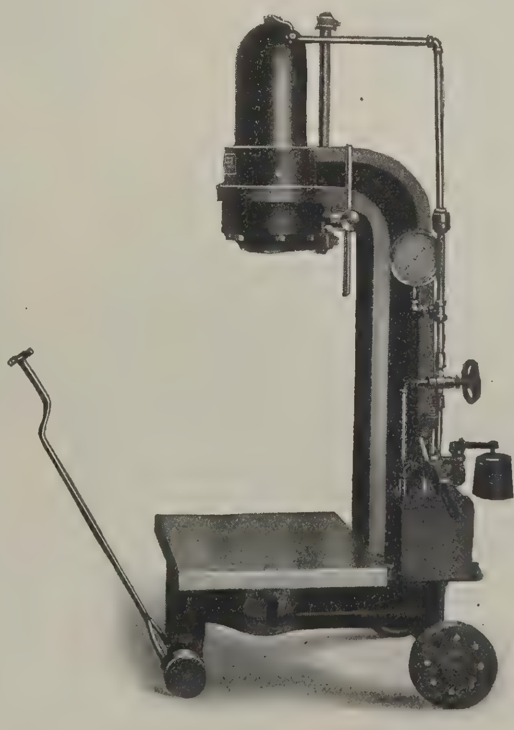

Fig. 2. Forcing Press built for Purdue University Experiment Station

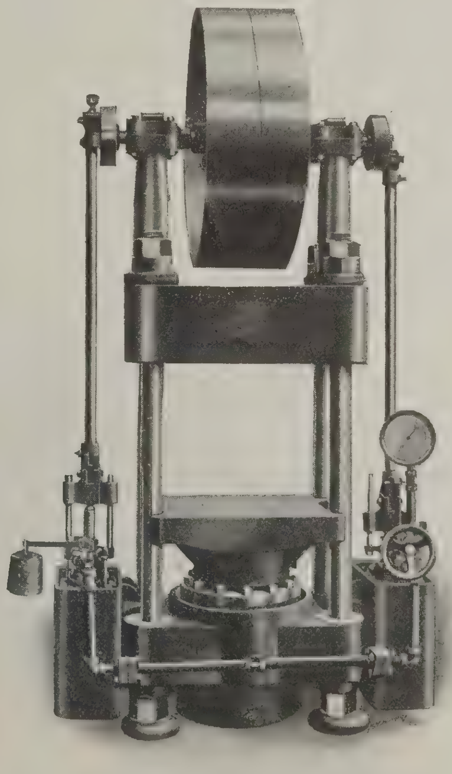

Fig. 3. Forming Press designed for Heavy Work

guard against overload. The power attachment is very simple and is located where it will not interfere with the operation of the press in any way.

EDGEMONT PLATE-TYPE FRICTION CLUTCH

The plate-type of friction clutch shown in Figs. 1 and 2 is an addition to the line of friction clutches manufactured by the Edgemont Machine Co., Dayton, Ohio. This friction clutch consists principally of three disks, enclosed in an outer casing provided with a hub on which the pulley or pulleys are held. (A two-piece sheet steel pulley is shown in place in Fig. 1). As shown in Fig. 2, the outer casing is provided with an internal rib, slotted to fit two keys formed on the "floating" disk which is faced on both sides with "burn-proof" brake lining. This central disk is free to "float," but cannot rotate independently of the outer casing.

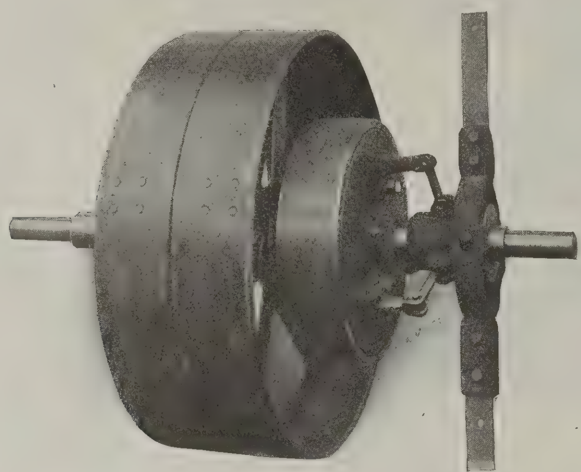

Fig. 1. Edgemont Friction Clutch with Pulley attached

The lever plate to the right (see Fig. 2), is provided with lugs, and is also furnished with a hub to which the plate to the left, is keyed, but is free to slide laterally when operated by the studs and levers shown. These two plates form the outer friction members of the clutch, and when brought into contact with the friction surfaces of the "floating" disk, rotate the outer casing and consequently the pulleys which are held on it. The lever plate which is held to the countershaft by a set-screw or key is drilled to receive three studs, provided with adjusting nuts, and held in the plate to the left. These studs are pulled out by the shoe ends of the levers. which are held in the lever plate and operated by the other three levers, sliding sleeve and shifter.

Now, when the shifter rod is forced to the left, it forces the sliding sleeve inward "expanding" the levers, and through the medium of the cam ends of the levers in the lever plate, pulls out the studs, drawing the plate in and exerting a friction between the three surfaces. Then as the lever plate is held to the countershaft, it follows that all the members of the friction clutch rotate when held together by the friction exerted between their surfaces. When the shifter rod is forced to the right, the action on the levers is just the reverse of that described, and as coil springs are interposed between the inner surfaces of the two outer plates, they are automatically separated when the studs are allowed to go back. The adjusting nuts on the studs are used to give the desired amount of friction required for driving.

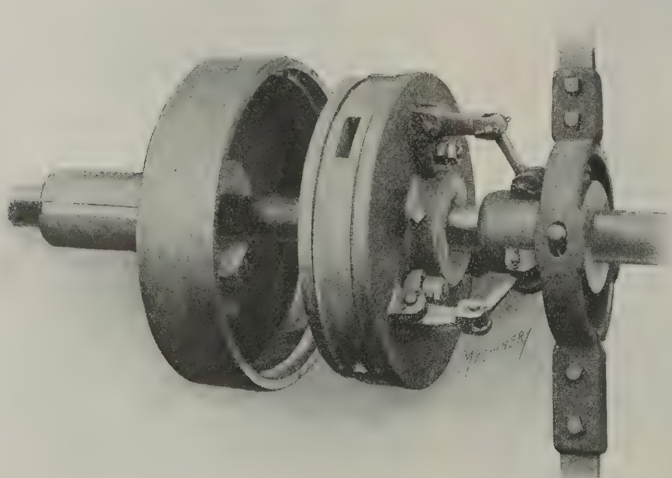

Fig. 2. Details of the Clutch Mechanism

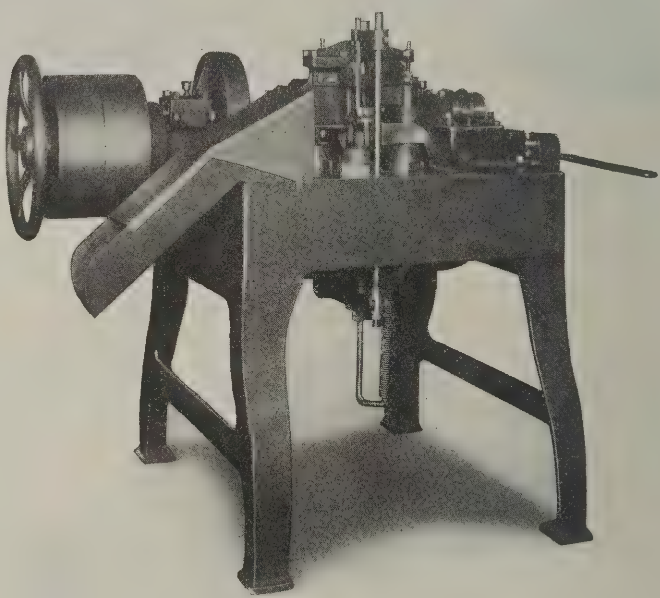
One feature of this clutch, which is especially commendable, is that its friction plates do not require oiling. The friction lining can also be renewed without removing the clutch from the shaft. This clutch can be operated at high speeds, and is suitable for very heavy duty. It can be applied to line-shafting, countershafts, etc., and is furnished in either the extended sleeve type (shown in Fig. 2), or with the cut-off coupling; this type is used for connecting two line-shafts, and enables one section of the "line" to run while the other shaft is stationary, or when the clutch is "connected" both shafts can be rotated.

BLISS AUTOMATIC TRIMMING AND CURLING MACHINE

A special machine recently designed and built by the E. W. Bliss Co., 5 Adams St., Brooklyn, N. Y., for trimming and curling the flanges of drawn cups, is shown in the accompanying illustration. The machine consists of a vertical turret with six spindles, each of which is equipped with a chuck. The spindles are revolved continuously by spur gearing, and the turrets intermittently by a Geneva movement. The operator places a cup on the chuck as it appears in front of him; the chuck then moves in position for the trimming cutters. There are two rotary cutters which are mounted in a slide and driven by a chain and sprockets. The slide moves by cam action in toward the chuck and the flange on the cup is trimmed. The scrap is discharged through the machine.



Bliss Automatic Trimming and Curling Machine

The curling of the edge is done at the two succeeding positions. When the first of these positions is reached, the edge is started, and at the next position, it is finished. For all three positions, the blank is held onto the chuck by an upper spindle which descends and clamps the blank after it has been placed in position. The discharge of the blank is effected by means of two fingers. These fingers descend on the cup, gripping it at the edge and lifting it up until a third finger strikes it; this throws the cup in a horizontal direction into the discharge chute.

The machine is semi-automatic, as the operator simply places the cup on the chuck and the machine does the rest. The capacity is about 30,000 cups in ten hours, and it will take either straight, taper, or spherical shells up to 3 inches diameter by 1½ inch high.

BRADFORD HEAVY PATTERN LATHE

The Bradford Machine Tool Co., Cincinnati, Ohio, is building a new 18-inch heavy pattern, quick change gear lathe. One of the interesting features of this lathe (a general view of which is shown in Fig. 1) is the back-gear speed-changing mechanism. In previous designs, two friction clutches for engaging the medium and large back-gears, were placed directly on the back-gear sleeve. In this design, only one friction clutch is required, which has the advantage of engaging the higher speed of the cone, as well as giving two gear reductions for driving the lathe spindle when taking heavy cuts.

With the two-speed countershaft which is regularly furnished with the lathe, eighteen spindle speeds are available. The six fast speeds are obtained by locking the cone to the face gear and disengaging the back-gear in the usual manner. The method of obtaining the remaining twelve speeds will be more clearly understood by referring to the detail view of the headstock, Fig. 2. The cone pulley, by means of an expanding clutch ring in the left end, drives double cone gears with which the back-gears *A* and *B* are in driving connection. These latter gears afford two distinct drives for the lathe spindle, the drive being in each case through the clutch member *C*, the back-gear sleeve and pinion meshing with the regular face gear *G*. The clutch member *C* and the friction clutch member *D*, are engaged and moved simultaneously by the steel cross-piece *E*, which is caused to slide on a cylindrical

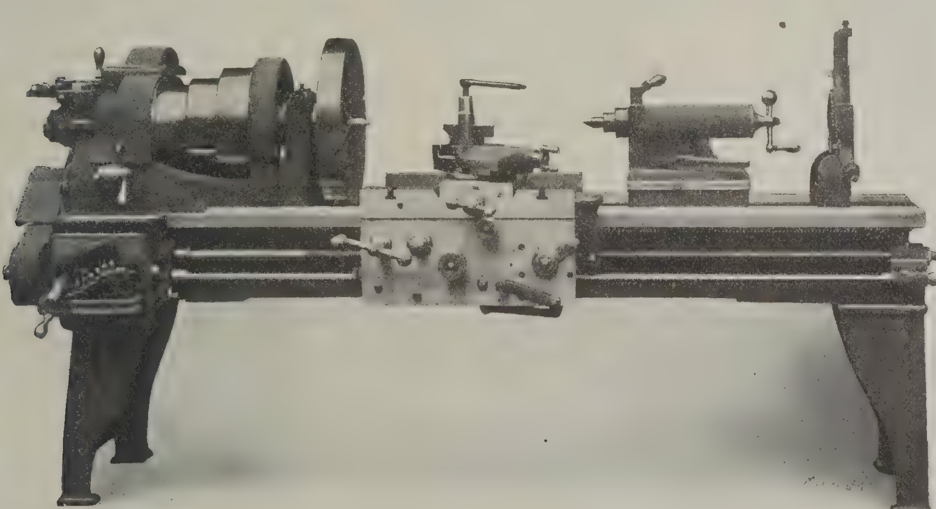


Fig. 1. Bradford 18-inch Lathe with Friction Double Back-gears

stud by handle *F*, and the connecting link shown. A movement to the right or left of clutch members *C* and *D*, causes the former to clutch first with either of the gears *A* or *B*, respectively, and, in both instances, the driving cone pulley is engaged in sequence by the friction clutch ring in the end of the pulley. The two back-gear speeds are available at all times without stopping the lathe. Lever *F* is provided with stop pins which prevent the action of this lever from subjecting any of the bearings or rotating parts of the lathe to end thrust.

Aside from the back-gear mechanism, this lathe is similar in its general construction to designs previously built by this company. The swing over the bed is 20¼ inches; over the rest, 11⅝ inches; and over the carriage, 13¼ inches. The size of the front spindle bearing is 3 1/4 by 5 1/16 inches, and the rear bearing, 2½ by 3¾ inches. The back-gear ratios are 10.95 to 1 and 3.31 to 1. The lathe will cut threads ranging from 3 to 46 per inch, including 11½ pipe threads. The spindle is made of high-carbon crucible steel and is mounted in adjustable taper bronze bearings. It extends through the hood,

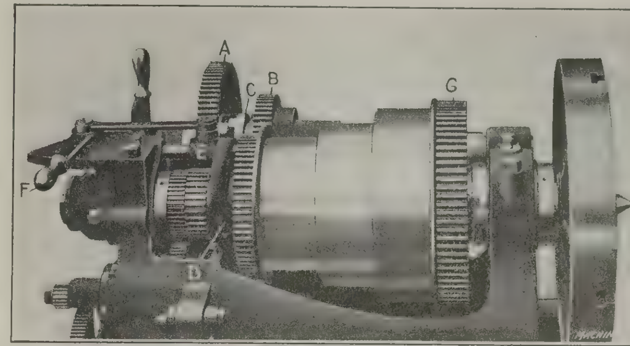

Fig. 2. Headstock of Bradford Lathe

allowing the use of draw bars and tubes for drawing attachments. The bed is of extra weight and depth and is webbed in two-foot sections, which gives great rigidity.

LA SALLE COMPENSATING QUADRANT CRANE

A one-ton "compensating quadrant crane" now being built by the La Salle Machine & Tool Co., La Salle, Ill., is shown in Figs. 1 and 2. This crane was designed for service on trucks and, at the present time, is made without a turntable; that is, the crane cannot be swung horizontally. A turntable, however, which will swing from 180 to 360 degrees, can be supplied. The lower end of the boom of this crane is segment shaped and has shrouded teeth which engage corresponding rack teeth on the base. These gear teeth are shrouded to the pitch line, not so much for strength, as to provide a rolling bearing for taking the vertical thrust due to the weight of the boom and load. The shrouding is machined on the outer surface, and the gear teeth are relieved of all vertical bearing stresses.

The position of the boom is changed by turning the crank and pilot wheel shown. The motion of the crank is transmitted to the screw through gunmetal bevel gears having a ratio of

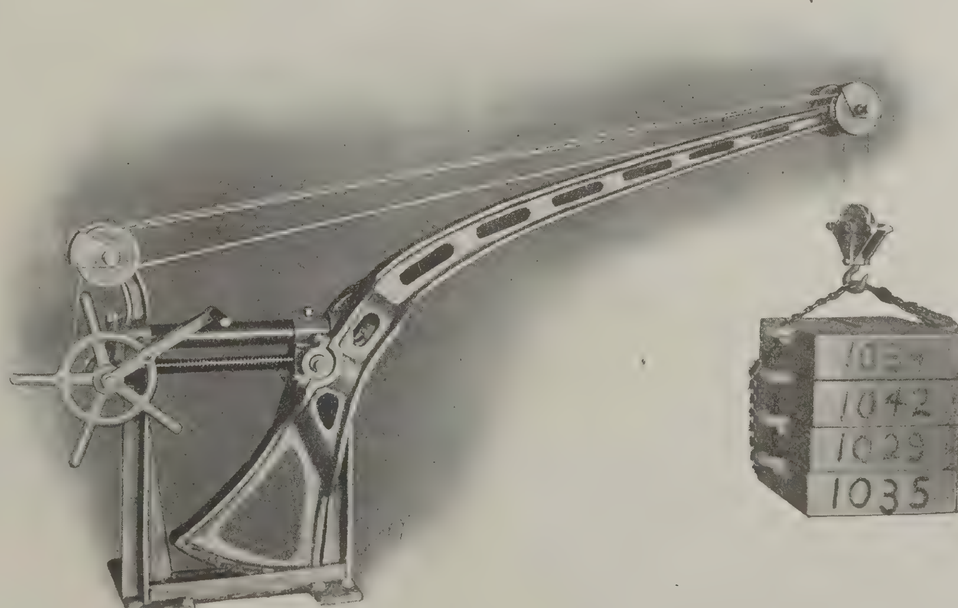

Fig. 1. La Salle One-ton Crane with Boom lowered

$1\frac{1}{2}$ to 1. The screw, in turn, engages a nut that is trunnioned in the boom and slides along a cylindrical rod above the screw. With this construction, one man can raise a load of one ton from the lowest to the highest position in thirty seconds.

Because of the compensating feature of the crane, the thrust on the screw is very slight and in some positions of the boom, the thrust is practically eliminated. The load also remains at about the same level whether the boom is in its lowest or highest position. The hoisting cable can be operated either by an electric hoist, in case the crane is mounted on an electric truck, or by a hoist designed to be driven directly from the transmission of a gasoline truck.

The frame, boom and nut are made of open-hearth steel castings. The tie-rod upon which the nut slides is made of cold-rolled steel covered with brass tubing. The screw is made of

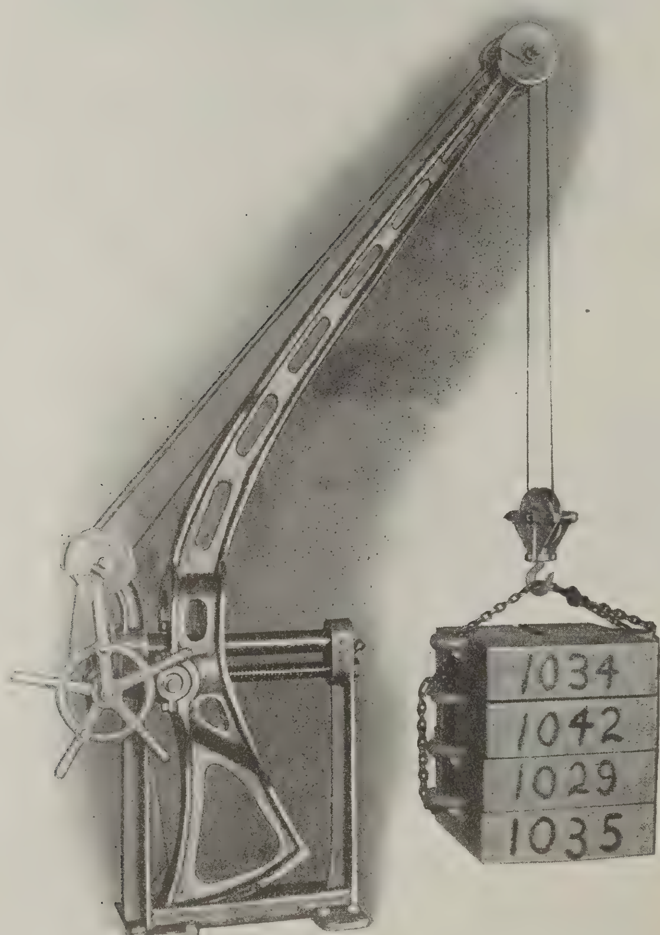

Fig. 2. La Salle Crane with Boom raised

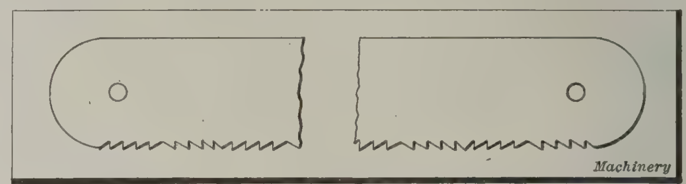
30 per cent nickel steel to avoid corrosion and is mounted in self-aligning radial and ball thrust bearings. The nut is lined with phosphor-bronze.

The figures on the weights (see illustrations) show the test load used on this crane. With this load, it is possible for one man, by means of the crank, to raise the boom from the lowest to the highest position without over-exertion. This crane has a maximum reach from the front of the frame, of 7 feet, and a minimum reach of 2 feet. The maximum and minimum heights are 9 feet 10 inches and 6 feet 2 inches, respectively.

REITLINGER DOUBLE-ACTION HACKSAW BLADE

A new type of hacksaw blade, recently placed on the market by Alex. Reitlinger, 201 William St., New York, is shown in the accompanying illustration. The design of this saw is decidedly novel. The teeth are arranged in groups of four, the teeth of each group being set in the opposite direction to those of the adjacent groups. The idea of this design is that the saw may be made to cut on both forward and return strokes. It will, of course, be evident that this type of saw is driven by a machine which is not equipped with means for lifting it out of engagement with the work on the return stroke.

It is claimed that the ability to cut on both the forward and return strokes gives this saw a materially increased cutting capacity. An idea of the capacity may be gathered from the fact that, in a recent test, a piece of $1\frac{1}{2}$-inch steel shafting was

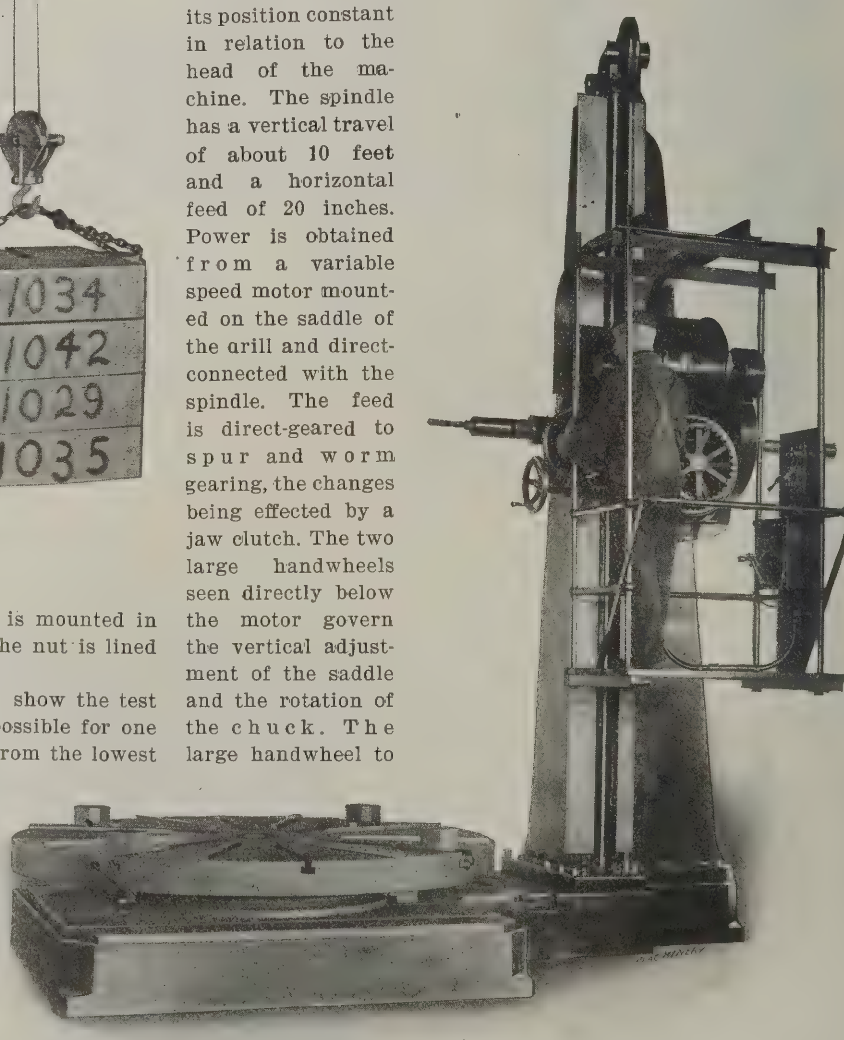


Hacksaw designed to cut on Both Forward and Return Strokes

cut in three minutes and thirty-three seconds. These saw blades are now being made $\frac{1}{2}$ inch in width with 16 teeth to the inch. It is also intended to make saws of this design having 11, 24 and 32 teeth to the inch; this range will provide for making saws of all necessary sizes for different classes of work.

BAUSH BOILER SHELL DRILLING MACHINE

A boiler shell drilling machine, in which the shell is held in a four-jaw universal chuck after being rolled and may be rotated from the operating position of the drill, is one of the latest products of the Baush Machine Tool Co., 200 Wason Ave., Springfield, Mass. The operator stands in a cage (see accompanying illustration) which moves on the column to keep its position constant in relation to the head of the machine. The spindle has a vertical travel of about 10 feet and a horizontal feed of 20 inches. Power is obtained from a variable speed motor mounted on the saddle of the drill and direct-connected with the spindle. The feed is direct-geared to spur and worm gearing, the changes being effected by a jaw clutch. The two large handwheels seen directly below the motor govern the vertical adjustment of the saddle and the rotation of the chuck. The large handwheel to the left controls the quick adjustment of the spindle and the small one in front of it governs the clutch. The handwheel on the shaft parallel with the spindle provides for a hand feed for hand drilling or facing.



Baush Boiler Shell Drilling Machine

The machine is provided with roller and ball bearings

throughout so that its operation is extremely light and sensitive, although the machine itself is of extremely massive construction, having a gross weight of approximately 30,000 pounds. The saddle is accurately counterbalanced and is raised and lowered by means of a screw which precludes the possibility of its dropping. The chuck has a capacity for shells ranging from 36 inches to 72 inches in diameter and up to ten feet in length; by reversing the work end for end, the capacity of the machine may be increased for work 20 feet in length. The chuck and its operating mechanism is a self-contained unit, so that the chuck may be lifted off the table and replaced again without the necessity of adjusting any gearing. The screws are equipped with ball thrust bearings which makes them easy to operate. The table is provided with T-slots so that it may be used for strapping down ordinary pieces to be drilled.

The machine stands 16 feet 1½ inch in height and the overall length is 14 feet. The top working surface and bed is approximately 7 feet square.

SHAW FIXED-TONGUE SWITCHES FOR MONORAIL CRANE SYSTEMS

An important improvement in the construction of monorail crane systems, in the form of a fixed-tongue track switch, has recently been made by the Shaw Electric Crane Co., Muskegon, Mich. The advantage of this fixed-tongue switch over the old-fashioned moving-tongue type, lies in the fact that it does not have to be set for the desired direction of travel. As the name implies, there are no moving parts to this switch, but it is still possible for the operator to select his route.

As the fixed-tongue switch does not have to be set for a change of direction, there is neither delay nor expenditure of effort for this purpose. Trolleys run through the track switch in all directions without stopping, and as there are no open ends of track, a serious source of danger has been eliminated. Reference to Fig. 1 will show that the two I-beams constituting the main or straight-through track and the third I-beam constituting the spur or curved track, terminate near the point of tangency of their center lines, and have a cast-steel extension piece or tongue rigidly secured to them. The projecting portion of this tongue is on the same level with the bottom flange of the I-beam and is a continuation of it. The tongues are so shaped that open slots are left between them through which the truck sides of the trolley pass in moving over the switch.

When the operator approaches the track switch at which he desires to run from the main line to a spur track, he pulls the steering lever which is located on the trolley near the controllers. This raises a horizontal roller to a position in which it engages a curved rib on the under side of the central tongue switch; the leading truck then swivels and is diverted onto the spur track. The trailing truck is guided onto the spur track by a positive and very simple means which is not dependent upon any action taken by the operator. No steering is necessary to return from the spur to the main line or to run through a switch on the main track in either direction.

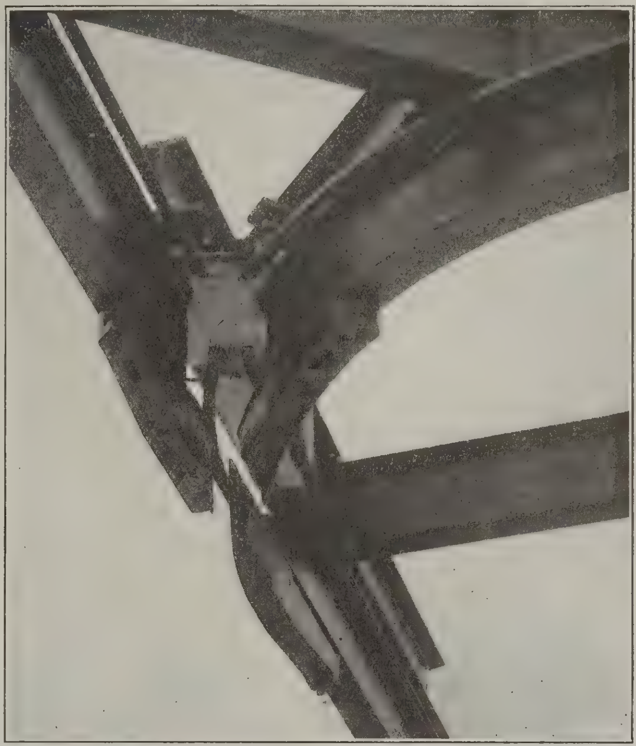


Fig. 1. Arrangement of the Shaw Fixed-tongue Track Switch

The details of the trolley design have been carefully worked out to secure a maximum efficiency of operation. Steel is employed in the construction of the main frame, the truck sides, the gears, and in all other parts where the weight of the load becomes effective, except in the rope drum and other compression members. The sizes of wire rope employed are especially liberal in proportion to the load, and the hook is a steel drop-forging which swivels on a ball bearing. Convenient

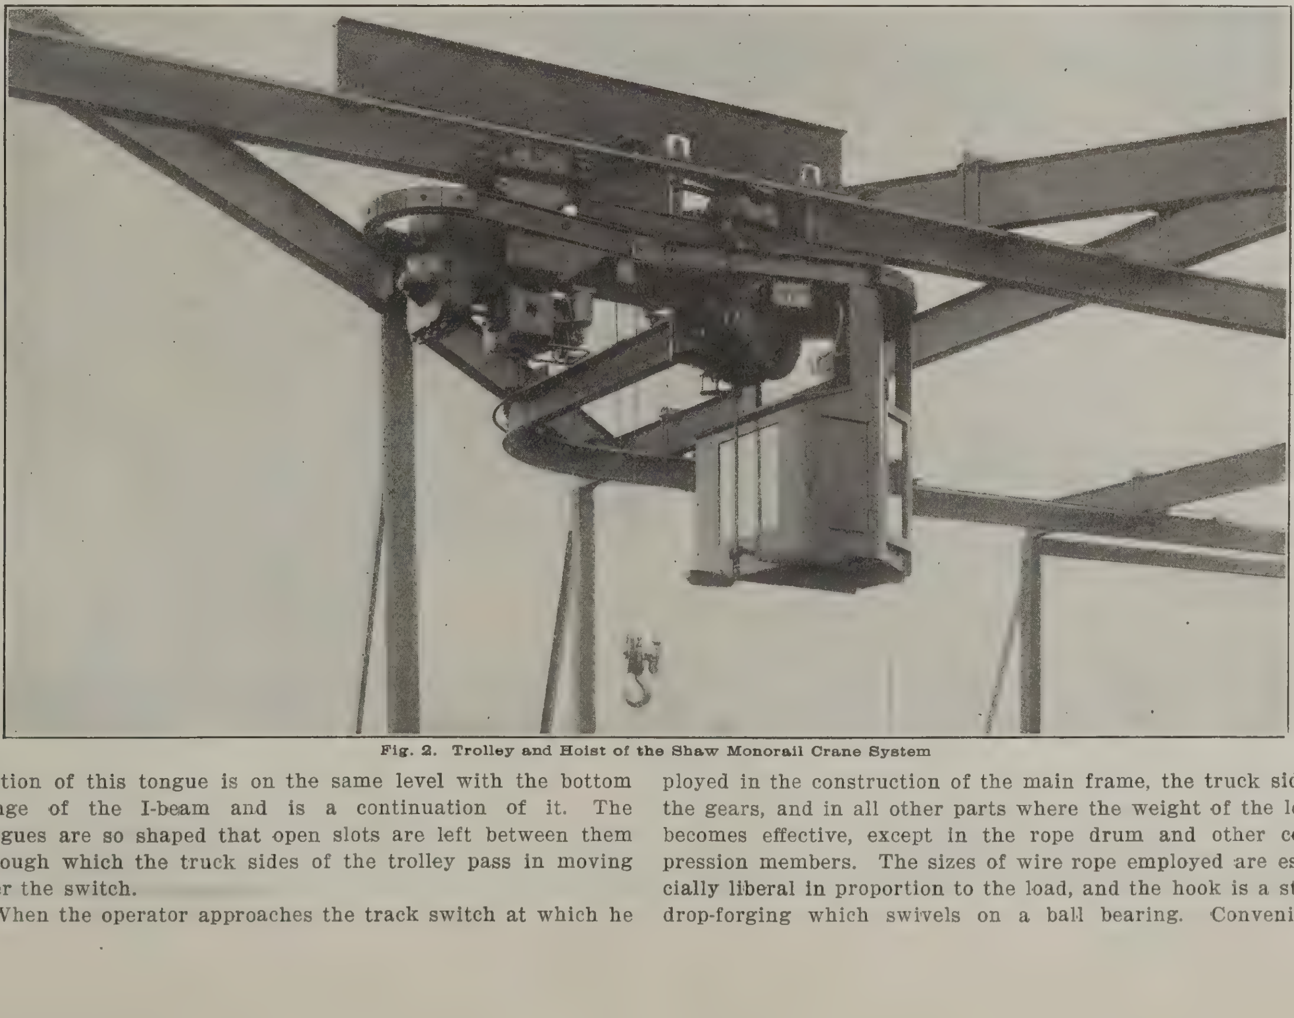

Fig. 2. Trolley and Hoist of the Shaw Monorail Crane System

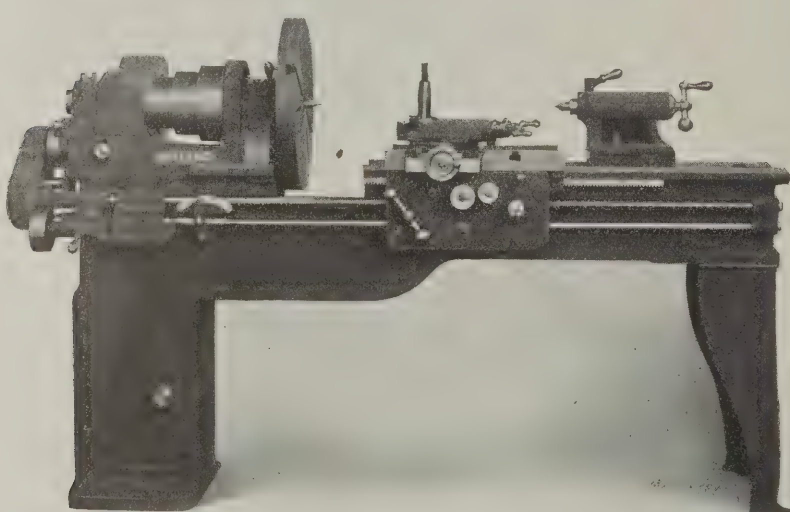
facilities have been provided for inspecting all internal parts without undue loss of time.

Curved buffers are provided at both ends of the trolley, forming a simple provision against collision with other trolleys, whether on curved or straight sections of the track. The hoist is equipped with motor and load brakes, the latter being of the multiple disk type and located in the hoist gear case. An automatic limit switch is also provided to prevent the lower block from being accidentally wound up into the trolley machinery. The motors have been designed especially for monorail work and embody the latest features applied for this class of service. The cage is arranged with a seat for the operator and all appliances necessary for giving him the requisite control over the crane.

WILLARD GAP-BED ENGINE LATHE

The gap-bed engine lathe illustrated herewith is built by the Willard Machine & Tool Co., Cincinnati, Ohio. This lathe is so designed as to make it suitable for both jobbing and manufacturing purposes. By removing the filling piece from the bed, the lathe may be made to handle work 21 inches in diameter up to 6½ inch face. When the filling piece is replaced, the lathe is transformed into a standard engine lathe which swings 13½ inches over the shears and is just as convenient to operate as any standard lathe of this type.

The headstock is of massive construction having a bearing of 21½ inches on the bed. The spindle is made of 60-point



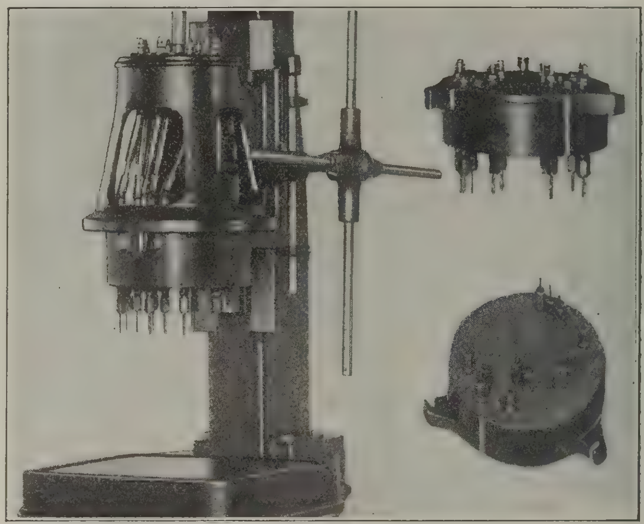
Willard Gap-bed Engine Lathe

carbon crucible steel; the front journal is 2⅝ inches in diameter by 4 inches in length, and the rear journal is 1 13-16 inch diameter by 3 inches in length. The bearings are of phosphor-bronze, carefully scraped to fit the spindle. The hole through the spindle is 1 5-16 inch in diameter, and is bored to fit a bushing for a No. 3 Morse taper. The tailstock spindle is 1¾ inch in diameter, the tailstock having a travel of 5¼ inches.

The carriage has a bearing 18 inches long on the V's. The bridge is 7¼ inches wide, and is equipped with a dial for use in screw cutting. The compound-rest is of new design, being unusually large and of particularly rigid construction. The crank handle for moving the carriage is at the left-hand side of the apron, which is an unusual arrangement for a gap-bed lathe. This handle is usually located at the right-hand side of the apron, where it is inconvenient for the operator to use it. A gib is attached to the carriage at the right-hand side of the apron for the purpose of stiffening it when it overhangs the gap. This lathe is furnished with 6, 7, 8, and 10-foot beds. It has a cabinet leg under the headstock end, an extra large faceplate, and the filling piece previously referred to, as part of its regular equipment. A cabinet leg for the tailstock end can be furnished as an extra.

CLUSTER BOXES FOR "NATCO" MULTIPLE-SPINDLE DRILLERS

The illustration presented herewith shows the head of a No. 9 multiple-spindle drilling machine, made by the National Automatic Tool Co., Richmond, Ind., equipped with a cluster box. Two other forms of cluster boxes are shown at the right-hand side of the illustration. These cluster boxes, or



"Natco" Drilling Machine equipped with a Cluster Box or Multiple Drilling Head

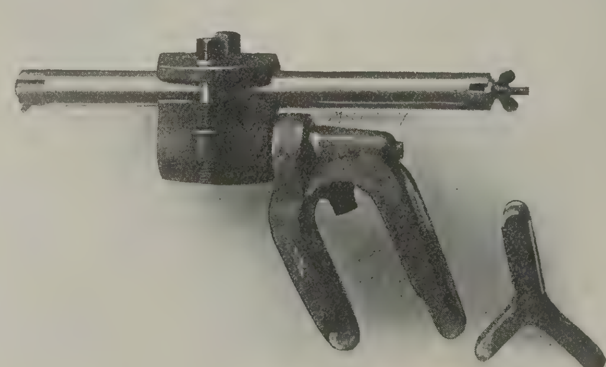
drilling heads, are used for special jobs of multiple drilling; they are made interchangeable, different cluster boxes being used for each class of work.

The boxes are driven by universal-joint spindles or a center-shaft drive. The universal-joint spindles can be detached quickly and are recommended in preference to the center-shaft drive. One reason for this is that it often makes it possible for simpler boxes or heads to be used. The universal-joint spindles also enable the adjustable rails to be used on the same machine.

With the cluster box equipment, a larger number of holes can be drilled than is possible when the machine is equipped with adjustable rails. The head has a circular range of 8⅜ inches, and the use of special cluster boxes enables this range to be increased. The machine is equipped with adjustable stops so that holes of predetermined depth can be drilled. The machine on which these drilling heads are used is the same as that illustrated in the New Machinery and Tools section for November, except that the one previously described was equipped with eight adjustable steel rails for carrying the drill spindles.

KRIEGER TOOL-HOLDER

The Krieger Tool & Mfg. Co., Grand Rapids, Wis., has recently placed upon the market the tool-holder shown below. The design has been developed to eliminate the spring which occurs with many other types of holders when taking



Tool-holder adapted to the Requirements of Heavy Work

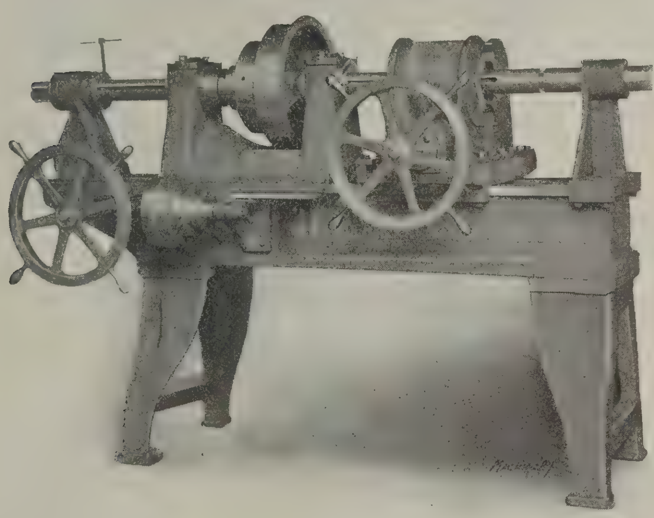
heavy cuts. It will be seen from the illustration that this holder has two shanks, only one of which need be used on light work. For heavy work, the ring is taken off the toolpost. One shank of the holder is then placed on each side of the tool-

post and the Y-shaped clamp goes through the slot in the tool-post. The three ends of this clamp engage with the shanks of the tool-holder, which is held securely in place when the set-screw is brought down upon the Y-clamp.

This tool-holder can be adjusted one inch below or one inch above the center of the lathe, and has been found particularly suitable for boring operations on stuffing-boxes and other classes of work where holes of different diameters are required.

UNDERWOOD ARMATURE AND AXLE BEARING BORING MACHINE

The machine illustrated herewith is a recent product of H. B. Underwood & Co., 1024 Hamilton St., Philadelphia, Pa., and is designed for boring the babbitted bearings of axle and armature shafts of the Westinghouse and General Electric motors used in electric car service. In addition to this work, the machine can be used for boring a variety of work such as large pulleys, etc. The design of this machine enables it to be operated by unskilled labor.



Underwood Armature and Axle Bearing Boring Machine

The handwheel toward the right operates a powerful self-centering chuck which holds and centers split or round bearings in correct alignment with the boring-bar, no particular skill being required to do this work both accurately and rapidly. The jaws of the chuck will take bearings ranging from 4 to 12 inches outside diameter, and special oil grooves can be cut in a bearing after the box is bored. The cutting tool is held directly in the bar, the latter being of ample strength to bore with a single-ended cutter. In order that extremely accurate boring may be done on bearings of harder material than babbitt, an outboard support and extension bar are provided.

The bearings in the headstock are made to compensate for wear without changing the alignment of the spindle, and wide-faced pulleys make it possible to bore large sizes of work without the use of gearing. The feed is automatic, with three changes, and there is a hand control with provision for a quick return of the spindle. It has been possible to shorten the bed of the machine through the provision of means for telescoping the feed mechanism under the headstock, the headstock forming a cover for the slide. During a recent test, a split babbitt-lined bearing of 5 inches bore and 11 inches length was bored out in less than one minute.

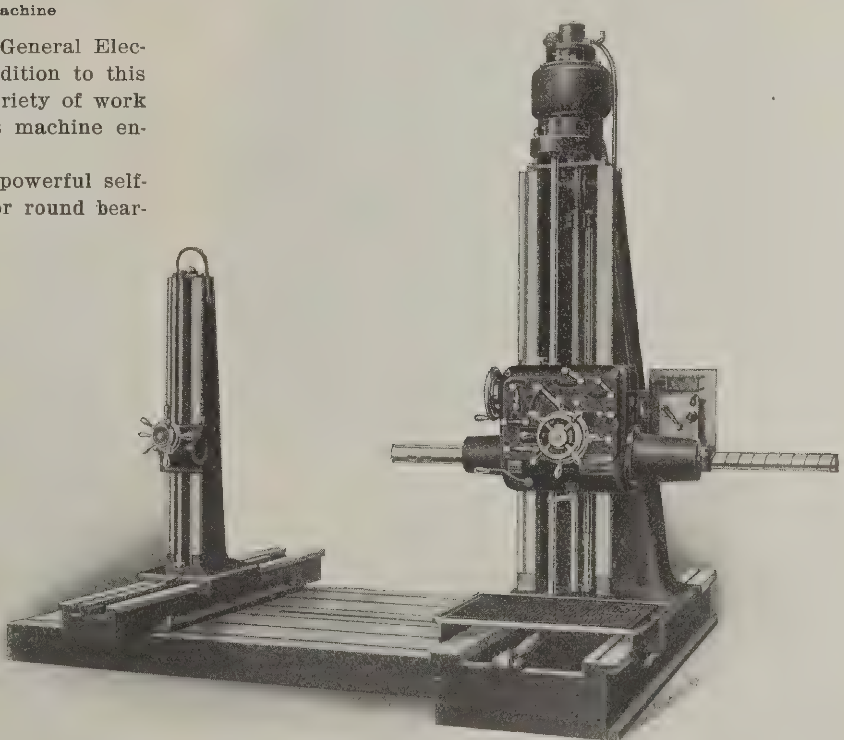
ROCHESTER BORING, MILLING, DRILLING AND TAPPING MACHINE

The Rochester Boring Machine Co., Rochester, N. Y., has brought out a new design of boring, milling, drilling and tapping machine. The operating levers and handwheels are located on the saddle within easy reach of the operator, so that the machine is convenient to work, and all changes of feed, speed and traverse in all directions, are obtained from a convenient position. The machine can be quickly started, stopped or reversed, independently of the motor or main drive. The saddle is of box construction, and is so designed that the entire operating mechanism is readily accessible.

The machine is regularly equipped with electric motor drive. The constant-speed motor is mounted on top of the column where it is out of the way of chips and dirt, and drives the vertical shaft, which transmits power to the driving mechanism enclosed in the saddle, through rawhide gearing. This arrangement simplifies the drive and gives a high power transmission efficiency. When belt drive is preferred, the machine is driven by a single pulley at the rear of the bed, the pulley being mounted on a splined shaft, which operates the vertical driving shaft in the column through bevel gears. The driving pulley is equipped with a clutch for starting, stopping and reversing.

The spindle is made of hammered, high-carbon crucible steel, and it is journaled in long taper bearings of phosphor-bronze, which are adjustable from the side and located at each end of the saddle, so that they are far enough apart to give a rigid support to the spindle. The feed and drive are applied between the bearings, the spindle being driven by two large spline keys fitted into a steel sleeve on which the driving gear is mounted. This sleeve is journaled in independent bearings, and clearance is provided between the sleeve and spindle to eliminate any vibration from the driving gears.

The concentric screw feed allows full traverse to be obtained without resetting. The method of feeding is through a long bronze nut engaging a square thread on the spindle. The nut only comes into contact with the sides of this thread and engages with the thread for the full length of the nut, so that an ample bearing surface is secured. The end thrust in either direction is taken on ball bearings of large diameter. The nut rotates at the same speed as the spindle when the feed is disengaged, and when the feed is applied, it is rotated faster than the spindle, according to the change-gear that is engaged; if the feed is reversed, the nut rotates slower than the spindle. This differential speed between the nut and spindle gives feed in either direction. The bar is controlled through positive planetary gearing by means of a handwheel, whether running or at rest.



Rochester Combination Boring, Milling, Drilling and Tapping Machine

A wide range of feeds and speeds is provided to meet all

requirements. The vertical milling feeds are provided for the saddle, and horizontal milling feeds for the column, independent of the boring feeds. All feeds are reversible and any desired change can be instantly obtained. The range of speeds can be readily changed to meet special requirements, giving faster or slower speeds of the same relative ratio. The power rapid traverse for the saddle, column and spindle is independent of the feeds. The power rapid traverse and feeds cannot engage together, and automatic limit stops are provided for every traverse in every direction.

GARDNER DISK AND RING WHEEL GRINDER

Fig. 1 illustrates a special disk grinder which is interesting because it is said to be the first disk grinder built with two spindles set parallel with each other. The rear spindle is mounted in the solid base of the machine and driven by a pulley belted to the countershaft in the usual way; this spindle has no lateral movement. The front spindle is driven from a pulley on the outer end of the rear spindle, a weighted idler being provided to maintain the required tension on the short

Fig. 1. Disk Grinder for finishing Parallel Surfaces in Different Planes

connecting belt. The front spindle is mounted in a head provided with a lateral adjustment which can be accurately regulated by means of the graduated handwheel shown beneath the front disk wheel. The table for supporting the work can be swung across the face of the wheel, but it is generally kept fixed in the position shown in the illustration. The purpose of this machine is to provide a rigid and accurate method of finishing two surfaces which must be parallel with each other, but in different planes. The method of regulating the adjustment of the movable spindle is particularly useful when it is required to have these surfaces at an exact distance from each other.

The novel features of the machine shown in Fig. 2 are the water shields and the angle-plates for holding the work on the lever feed tables. The hoods are of simple construction; they can be readily removed when adjusting or changing the ring wheels, and give free access at both sides for setting the work on the holder. It has been found that the wheels can be flooded with water when running at high speed, the pump for this purpose being set at the rear of the machine. The operation of the hoods is so efficient that scarcely a drop of water is thrown outside of the guards. The special angle-plates on which the work is held are provided with raised edges at the back and sides; these edges catch all water falling on the plate and return it to the pump. It is said that this

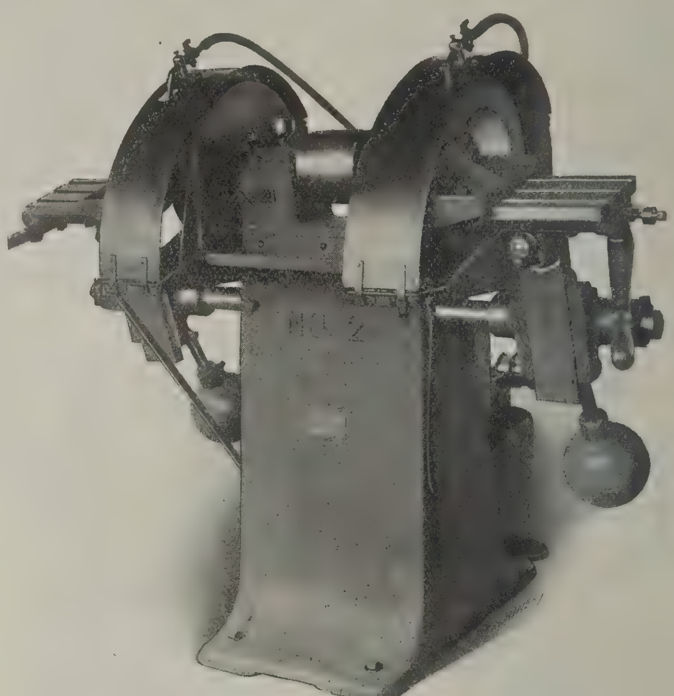


Fig. 2. Ring Wheel Grinder with Water Shields and Angle Plates for holding Work

equipment affords a particularly satisfactory method of applying water to grinding machines of this type. These machines are the product of the Gardner Machine Co., Beloit, Wis.

CALCULATING CHART

The accompanying illustration shows an interesting calculating chart that has been brought out by Mr. George M. Purver, 146 E. 8th St., Brooklyn, N. Y., for facilitating multiplications and divisions in cases where exact results are required. The slide-rule, as is well known, gives only exact

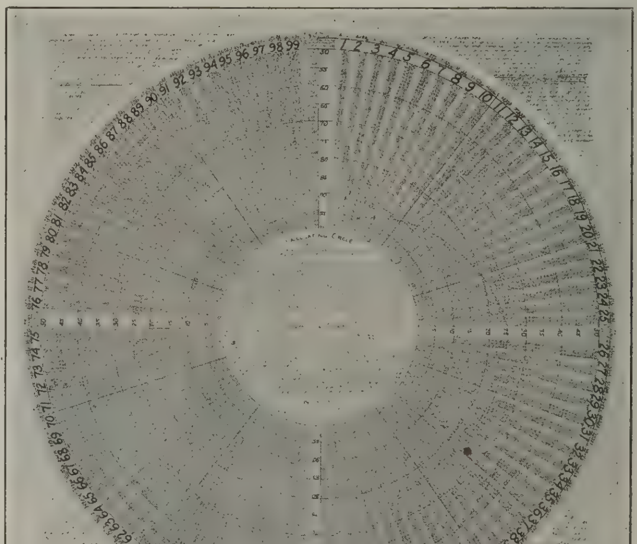

Chart for Rapid Multiplication and Division—Actual Diameter, about 15 inches

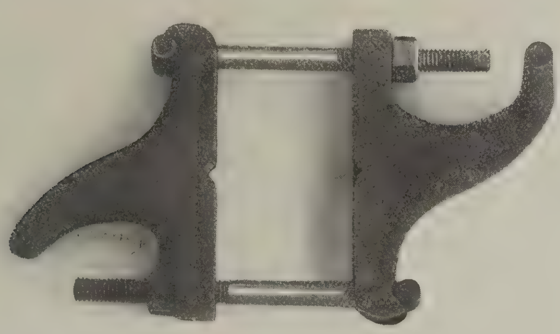
figures to very few places, and while it is satisfactory for most practical calculations where the assumed values themselves are approximate, there are conditions when the exact product is required. It is for cases of this kind that the calculating chart has been prepared. It gives instantly the product of all numbers of two figures only, and the product of a number of two figures with a number of four figures with

a slight calculation, which by training can easily be performed mentally. From a mathematical point of view the arrangement is rather unique, and there are several interesting points in the working out of the chart. Of course multiplications of numbers with any number of digets by other numbers of any number of digets can also be performed by writing down the results of the multiplication of any two figures by any other two figures, which shortens considerably the ordinary work of multiplication.

MICHAUD SAFETY LATHE DOG

The safety lathe dog illustrated herewith has recently been placed upon the market by Elmer J. Michaud, Willimantic, Conn. The clamping members of this dog are drop-forgings, held together by bolts in the manner shown. It will be seen

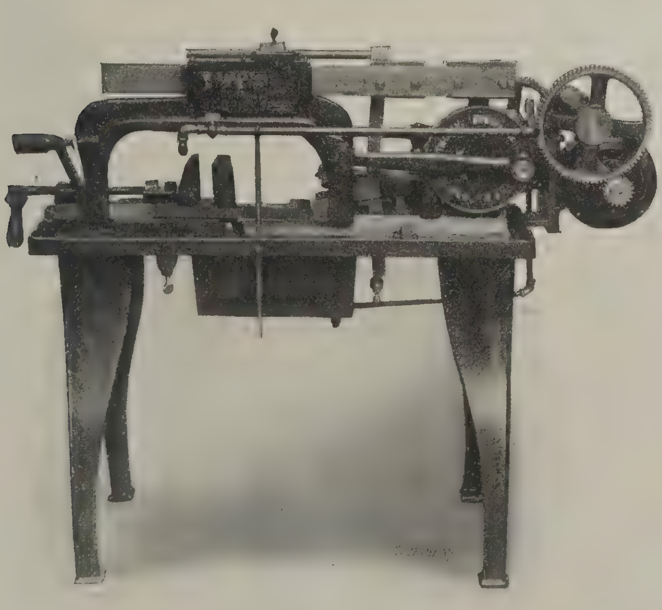


The Michaud Safety Lathe Dog

that the clamping members are provided with curved extensions which come out over the exposed ends of the bolts. The dog is mounted so that these extensions revolve ahead of the bolts, making it practically impossible for the operator's clothing to be caught or for him to be injured by the sharp edges on the bolt and nut.

ROBERTSON MOTOR-DRIVEN POWER SAW

The W. Robertson Machine & Foundry Co., Buffalo, N. Y., has recently equipped its No. 3 Economy power saw with a direct-connected motor drive. The method of attaching the motor to the saw frame is shown in the illustration, no drilling of extra holes being required for mounting it in place. The motor is back-geared and is a self-contained unit of standard



Robertson Economy Power Saw No. 3 equipped with Motor Drive

make; it is compound-wound and no starting box is required.

This machine cuts on the draw stroke and is equipped with this company's standard mechanical lift for the return stroke, which raises the blade from the work and greatly reduces the strain which it experiences in service. The maximum cutting capacity is 6 by 6 inches and the machine is so arranged that 10-, 12-, or 14-inch blades may be used. A friction band clutch in the driving gear provides for starting, and an automatic stop throws out the drive when the cut is completed. A rotary brass pump is used for pumping the lubricating fluid from the tank to the blade.

ROCKFORD HIGH-DUTY PRESS WITH AUTOMATIC BRAKE

The illustrations show a high-duty press manufactured by the Rockford Iron Works, Rockford, Ill., and also the patented automatic brake with which this machine is equipped.

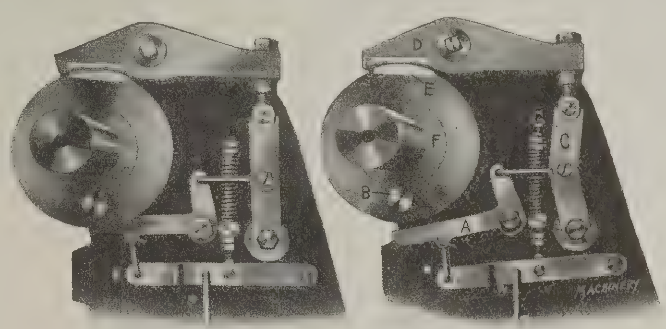


Fig. 1. Brake Mechanism of Rockford High-duty Press in the "Engaged" and "Released" Positions

The design of this brake has been developed with the view of saving a large percentage of the power which is consumed in operating some types of brake mechanism. The Rockford brake is automatic in its action and is applied only at the top of the stroke. The brake is not applied at any other point

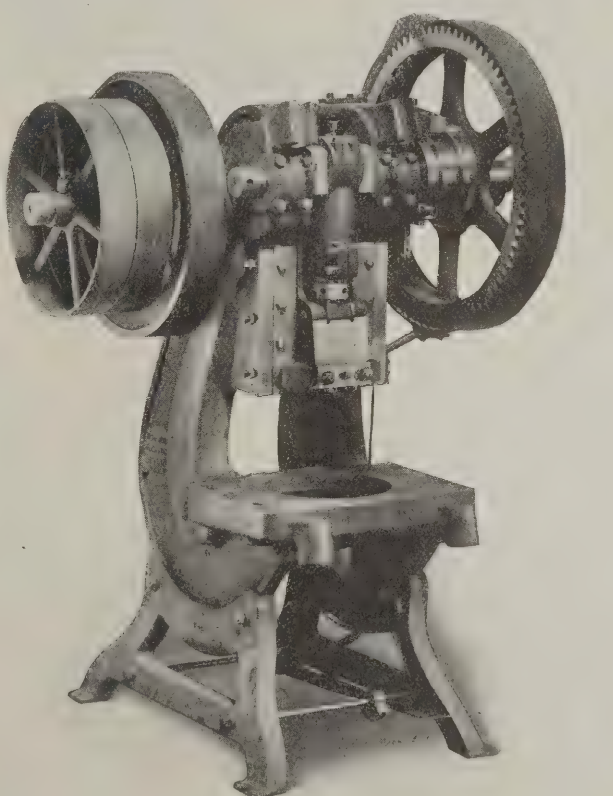

Fig. 2. Rockford High-duty Press equipped with Automatic Brake

during the shaft cycle so that friction losses are reduced to a minimum, only a sufficient amount of resistance being applied to stop the machine at the top of the stroke. The saving of power effected by this device in shops where a large number of presses are in operation will be appreciated.

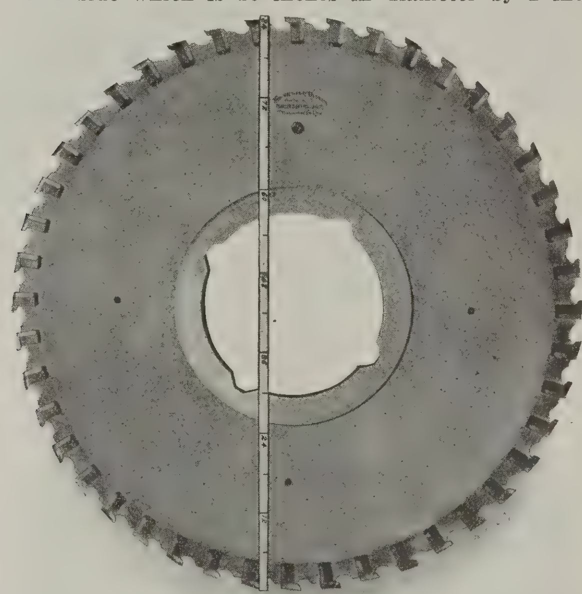
The action of the brake is automatically controlled by the treadle. When the treadle is depressed, the clutch release pawl *A* is drawn down, releasing the clutch pin *B* which is forced forward by a spring into one of the three hardened tool-steel contact points on the flywheel. Just before the clutch pin *B*

is released, and by means of the same pressure on the treadle, the toggle-joint C, which holds the brake D against a hardened tool-steel projection E on the driver F, is broken. This releases the brake D which is so held until the foot is removed from the treadle. The brake is placed on the right-hand side of the press so that all torsional strain on the shaft is eliminated, and this arrangement gives plenty of room on the left-hand side for the attachment of automatic feed equipment, oiling devices, etc.

HUNTER DUPLEX INSERTED-TOOTH SAW BLADES

The Hunter Saw & Machine Co., 57th and Butler Sts., Pittsburg, Pa., has recently manufactured two of the largest inserted-tooth, metal-cutting saw blades which have ever been placed upon the market. They have been given the trade name of "Hunter duplex," and are made from steel plates 1 inch in thickness and of special analysis to give the best results when subjected to the method of heat treatment used.

The finished saw is 84 inches in diameter, and has a collar on either side which is 26 inches in diameter by 1 inch in



Hunter Duplex Inserted-tooth Metal-cutting Saw Blade

thickness. These collars are riveted to the body of the saw and have four equally spaced keyways milled in them by which the saw blade is driven. Forty-four pockets are milled around the periphery of the saw and roughing and finishing teeth are inserted alternately in them. At the bottom of these pockets, the plate is drilled and tapped to admit a hexagon-headed brass screw which is used in setting the teeth to the proper height. These teeth are made of the best grade of high-speed steel, so that they have an ample cutting capacity, and each tooth is reinforced and rigidly held by a tool-steel wedge. An idea of the size of this saw may be gathered from the fact that the teeth weigh 1¾ pound each, the wedges ¾ pound each, and the saw blade 2000 pounds. These saws were designed for cutting 40-inch ingots, and an idea of their capacity may be gathered from the fact that they are capable of cutting 24-inch ingots in ten minutes. They are driven by a 75-H. P. motor.

NEW MACHINERY AND TOOLS NOTES

Bench Lathe: B. C. Ames Co., Waltham, Mass. A bench lathe equipped with a head that has an extra large spindle. The capacity of the machine is for work up to 2½ inches in diameter.

Pipe Wrench: Erie Stamping & Mfg. Co., Erie, Pa. A convenient form of pipe wrench made from a steel stamping and produced in such a way as to supply the demand for an adjustable pipe wrench at a moderate price.

Hollow Set-screw: Goodwin Hollow Set-Screw Co., Waterbury, Conn. A hollow set-screw designed to be driven in with a suitable wrench, but which has projections on its inner surface that make it possible to use a screw-driver in place of the regular wrench.

Motor-driven Buffing Lathe: Northampton Emery Wheel Co., Leeds, Mass. A motor-driven buffing and polishing lathe. The motor is completely enclosed and bolted to an adjustable bed, which has a vertical adjustment of 4 inches to provide for regulating the belt tension.

Automatic Wire Straightener and Cutter: F. B. Shuster Co., New Haven, Conn. An automatic wire straightener and cutter which has a capacity for lengths up to 67 feet and is said to be the largest machine of its type ever built. It is intended for cutting reinforcements for concrete flooring.

Metal Sawing Machine: Vulcan Engineering Sales Co., Chicago, Ill. A small metal sawing machine in which the saw blade is driven from the periphery by means of steel rolls journaled in removable steel bushings held in the double driving gear. The periphery drive makes a greater portion of the blade available for cutting.

Combination Saw and Rotary Planer: Vulcan Engineering Sales Co., Chicago, Ill. A combination saw and rotary planer mounted on a circular base. This machine is particularly suited to the requirements of structural steel shops. As it combines the functions of two machines in one, it should be a particularly useful equipment.

Horizontal Boring, Drilling and Milling Machine: Lucas Machine Tool Co., Cleveland, Ohio. A new size of precision horizontal boring, drilling and milling machine, known as model No. 31. This machine is similar in its essential details to preceding types built by this company. The new machine is the smallest one of the line.

Adjustable Boring Tool: Armstrong Bros. Tool Co., 313 N. Francisco Ave., Chicago, Ill. An adjustable boring tool in which the bar is made from high-carbon steel tubing. The cutter is held by a drop-forged eye-bolt which has a square yoke at one end to carry the cutter, and a threaded section at the other end for tightening the cutter in the bar.

Open Side Grinding Machine: Detrick & Harvey Machine Co., Baltimore, Md. An open side grinding machine similar in design to the open side type of planers. This machine is intended for grinding such pieces as railroad frogs, switches and crossings, safe and vault parts, and similar classes of work which cannot be handled with cutting tools.

Bench Filing Machine: B. C. Ames Co., Waltham, Mass. A new machine which is a modification of the preceding type manufactured by this company. In the new design, a bench countershaft has been added to the equipment to carry the belt out of the way of the operator, and there is a graduated swivel under the table for securing any desired angular setting.

Planing Machine with Reversing Motor: Woodward & Powell Planer Co., Worcester, Mass. A planing machine driven by a reversing motor which has the Triumph-Monitor system of control. The machine is without overhead gears, belts, belt-shifter or driving pulleys, the motor being coupled to the driving shaft. The controller is fastened to the planer housing.

New Cage-operated Traveling Wall Crane: Cleveland Crane & Engineering Co., Wickliffe, Ohio. A new type of cage-operated electric traveling wall crane which has a capacity of ten tons and consists of two main parts—the bridge proper and the trolley. An important feature of this crane is that the bridge is driven by two motors, which eliminates the use of a through lineshaft and simplifies the design of the machinery.

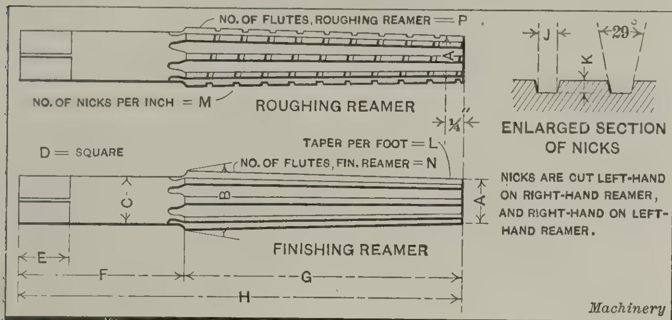
Broaching Machine with Motor Drive: J. N. Lapointe Co., New London, Conn. A motor-driven machine adapted for broaching various shaped holes of small sizes, which has the motor mounted on the same base with it. The switch is conveniently located on the front of the countershaft bracket and the machine has a large ball thrust bearing to receive the pressure from the screw; the countershaft is also equipped with ball bearings.

Geared Double Facing Head: Rochester Boring Machine Co., Rochester, N. Y. A geared double facing head for use on the Rochester horizontal boring machine. The faceplate on the head is geared to run slower than the bar and is made independent of it. The facing head on the outer support is also geared and runs slower than the boring-bar; this head is driven by the extension of the boring-bar through gears at the back of the column.

Automatic Screw Machine: Flanders Mfg. Co., Pontiac, Mich. An automatic screw machine which is the design of Mr. John J. Grant, and has a number of novel and interesting features. This machine has four spindles, all of which are at rest during the non-cutting movements of the machine. These spindles are fitted with the usual type of spring collet, but the stock is fed through without the intervention of feed sleeves or shells. Six changes of feed for the cutting movements are obtained by a simple gear-box, and the cams on the machine never require changing to suit different diameters and lengths of work. There is a constant rate of speed for the return movements, for feeding the stock and for the forward movements of the turret, regardless of the cutting speed. The same countershaft which drives the spindles provides for the constant speed drive, but in the case of the spindles, there are three rates of speed. This number may be doubled by transposing the pulleys on the countershaft and machine.

TAPER REAMERS FOR STANDARD TAPER SOCKETS

Several years ago, some tables were published in MACHINERY giving general dimensions of taper reamers for standard taper sockets, including Morse, Brown & Sharpe, and Jarno tapers. Complete data for the making of these tools have not, however, been published in any form, as far as the writer knows. The accompanying tables, therefore, have been prepared with an idea of placing on record all the information that might be required by the toolmaker in making these tools. Special attention is called to the information given for the making of the roughing reamers, which are made smaller in diameter at the small end than the finishing reamers, and which are provided with a groove cut like a thread on the cutting edges, as indicated. The purpose of this groove is to break up the chips. On ordinary right-hand reamers this groove is cut left-hand. The sides of the groove incline at an included angle of 29 degrees. The object of selecting this angle is to make it possible to use a tool having the same included angle as an Acme threading tool for grooving. A tool with inclined sides is preferable to a square tool on account of the greater ease with which the grooves or nicks can be cut. While the shape and exact dimensions for these grooves may seem to be rather unimportant details, yet in manufacturing it is important to so standardize all operations that standard tools can be used. The corners of the grooving tool are slightly rounded to prevent hardening cracks.



Notation used in Tables of Taper Reamers

In addition to the standard Morse, Brown & Sharpe, and Jarno taper reamers, dimensions of reamers for sockets for the so-called American taper are also included, so that the tables cover practically all reamers used for making taper sockets.

Tables of this kind are of value not only to the toolmaker who may be called upon to make a reamer for a standard taper socket, but also to the user of these tools, who often needs to find out certain dimensions on tools he is about to order, and to the machine designer, who has to keep in mind the tools used in the manufacturing processes. It also enables the designer to choose such tapers for taper locking bolts, etc., as can be reamed with standard taper reamers.

TABLE I. TAPER REAMERS FOR BROWN & SHARPE STANDARD TAPER SOCKETS

STRING DROP-FORGING

BY J. W. JOHNSON*

String-forging is the most economical way of drop-forging small pieces like those shown in Fig. 4. By string-forging is meant the forming of small pieces in a string, without cutting off each piece separately after forging. A section of untrimmed work made by string-forging is shown in Fig. 1. The advantages of handling work by this method are first that it is an extremely rapid operation, in that more forgings can be made per day, and, moreover, there is less liability of the

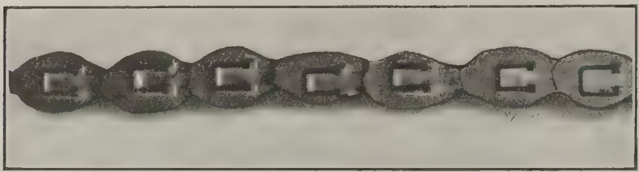

Fig. 1. Section of a String of Sixteen Forgings made in One Heat

drop-forger spoiling work by misplacing it in the dies than when transferring from the breakdown to the face impressions when drop-forging in the ordinary way. Likewise in trimming, the work may be handled more rapidly than is the case when each separate piece must be picked up and laid in the dies separately. While relatively few forgings can be string-forged, still many of the smaller forgings, say under three inches square in size, can be handled successfully in this way. No breakdown can be employed when string-forging is resorted to, for it would be obvious that the time gained by the string-forging method would be lost if it were necessary to shift the string to the breakdown for every forging. From the above it will be gathered that any forging which may be forged without a breakdown, if it does not exceed the approximate limits of three inches square, may be advantageously made by string-forging.

The small yoke for which the dies shown in Fig. 2 were constructed is made of steel. It is approximately ¾ inch wide and 1 inch long, the bosses on the ends being 5/16 inch in diameter. The dies used for this job had faces five by seven inches and the thickness of the blocks was seven inches each. Care should be taken in selecting blocks for string-forging dies for, even though the forgings be very small, the faces must not be too small or the amount of "beating surface" will be insufficient, and thus shorten the life of the dies. As will be seen, the dies are fitted with finishing impressions, and there is also a cut-off at the corner to sever the strings of completed forgings.

For making these forgings, 7/16 inch round steel bars were used. The advisability of using round stock might be questioned, but owing to the large variety of rectangular sizes that would accumulate if other than round stock were employed, it is better to use round stock, even though in some instances an extra blow is required. The bars, of lengths convenient

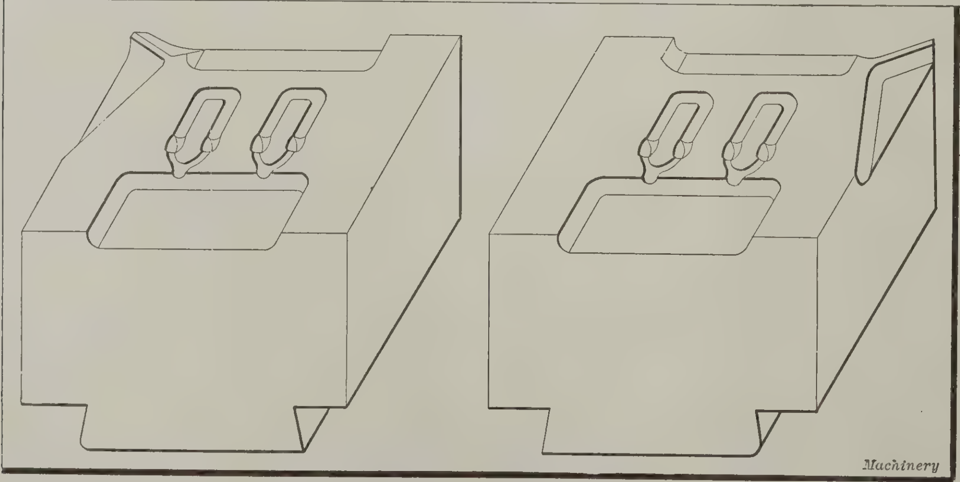

Fig. 2. The Drop-forging Dies

for handling, are heated and the forgings made by striking in the finishing impressions. From two to three blows complete each forging, after which the string is advanced to bring the completed work to the clearance cut at the rear side of the dies, thus permitting another piece to be forged. As many forgings as possible are made in one heat, leaving them all on the string. At the end of the heat the completed string of forgings is cut from the bar and the remainder of the bar is reheated to form another string.

For this work a 500-pound board drop was employed, striking from 30 to 40 blows per minute, and at this rate of speed from 4000 to 4500 completed forgings per day is the output. Work like this is best handled on a board hammer in preference to a steam hammer, and in fact, in the writer's opinion, steam hammers are inferior to board hammers except in the case of very large presses. The constant breakage of parts on a steam hammer is a great source of trouble.

For trimming these forgings from the string, the die shown in Fig. 3 is employed. This trimming die does not differ from the ordinary trimming die except that it is cut away on both ends in order to permit the rest of the string to clear. The tongue which trims the center of the yoke is dovetailed into the die as a separate piece, and in case of breakage, it is only necessary to fit a new center piece. In trimming, the first forging in the string is fitted over the die opening and the

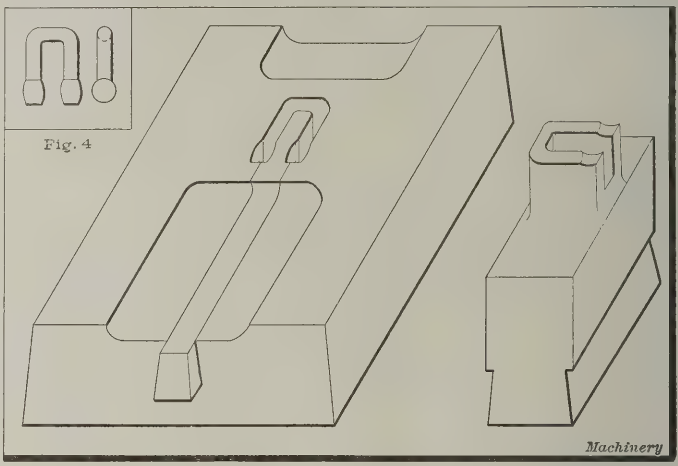

Fig. 3. The Trimming Die Fig. 4. Details of Forging

press tripped, after which the string is advanced until the second forging is in line and so on until all of the forgings are trimmed from the strip.

Another method of string-forging that is often employed when the work is very small is to provide the forging dies with three impressions in a row, so that three forgings are completed at a time. In trimming such work, however, the pieces are treated separately.

* * *

The Cleveland Planer Works uses chrome-nickel steel having a tensile strength of about 140,000 pounds per square inch of section, for the tool-holding studs in clapper-boxes. The ultimate breaking strength and tensile strength of this chrome-nickel steel is about the same, which is a peculiar advantage for tool-holding studs because of the abuse to which they are often subjected. Often a tool will be clamped close to the studs on one side and the nuts on the near studs will be screwed down first. Then when the nuts on the outer side are screwed down, a heavy stress is thrown on the first studs tightened, sufficient oftentimes to stretch or break them. If made of low carbon steel they will be stretched out of lead, thus causing great trouble, but if made of steel having equal elastic and tensile strengths the studs break before stretching much out of lead.

EFFICIENT PRODUCTION OF CYLINDRICAL WORK*†

SHOWING HOW TOTAL EFFICIENCY CAN BE INCREASED BY ROUGH LATHE TURNING PREPARATORY TO CYLINDRICAL GRINDING

Turning is one of the oldest of the mechanic arts, and the lathe is one of the oldest metal working machines; but the lathe has been a very inefficient tool until the present time. We now have lathes so designed that they can be made efficient. As a rule, however, we are not using the modern high power lathes as we should, and are losing what they were designed to save, *viz., time;* while we use them as roughing machines, we also use them as finishing machines.

Most cylindrical work must finally be brought to a size within small limits, and be truly cylindrical within still smaller limits; this led mechanics to study the art of refined turning. When this art had reached a high degree of refinement, men discovered that it did not satisfy them, and cylindrical grinding was introduced to give greater refinement than could be obtained with the lathe. At that time, it was the somewhat natural conclusion that the grinding machine should take up the work after the limit of refinement had been reached with the lathe, and the early grinding machines were designed with this object in view. Later, however, it was shown that ground cylindrical work could be produced at a cost no greater than the turning alone, by simply using the lathe to remove the larger portion of the metal and not at all as a means of refinement. The entire responsibility for refinement of the work was then transferred to the grinding machine.

While some understand this method and are using it to produce cylindrical work efficiently, the great majority are still under the spell of tradition, and are turning what they call "good work"—work that shows care and skill on the part of the operator and accuracy in the lathe. Such care in producing turned work is even more senseless today than the old-time practice of shaping acorns on screw heads, and putting cast-iron eagles on the tops of machine tools. In the former case, the grinding machine removes all trace of the lathe's accuracy and the operator's skill in a moment of time, while the latter remained for years to gratify the taste of those who had an eye for such artistic embellishment. The developments of the last few years have brought us face to face with the fact that, except in rare cases, efficiency in the production of cylindrical work means the use of the lathe as a roughing tool only, and the adoption of the modern grinding machine for refinement.

Most lathe operators and foremen seem to understand roughing to be simply turning work a few thousandths over the finish size. In reality, this is not roughing at all, but simply turning to a certain degree of refinement. It is difficult to secure roughed work from lathe operators, *i. e.*, work that is not in any sense refined. Tradition causes most operators to consume much more time than would be necessary if the work were merely roughed; sometimes they understand roughing, but confuse it with a certain degree of refinement. Roughing is not refinement of any degree, and refinement does not necessarily mean perfection. There are many degrees of refinement, but never degrees of accuracy or perfection. Accuracy and perfection are final and fixed; they have no limits.

Those who would produce cylindrical work efficiently must recognize the fact that different cases require different degrees of refinement; but whether the work requires a very low degree of refinement or a degree closely approaching accuracy, the lathe work to be efficient, should be the same, *viz.* as *rough* and as *cheap* as it is possible to make it. The lathe of today should only be a roughing tool, and the grinding machine a refining tool only—not a perfecting tool. Some grinding machines may produce greater refinement than others, but none can produce exact and perfect cylinders. While it is true that many mechanics look upon a high degree of refinement as accuracy, and speak of it as such, it is evident that this is not the case. When these facts are generally recognized, there will be greater efficiency in the production of cylindrical work. Because these facts about roughing and refining are not well understood, and because men do not combine the lathe and grinding machine in a well defined and efficient manner, the machine industry and railroads are losing large sums of money every year.

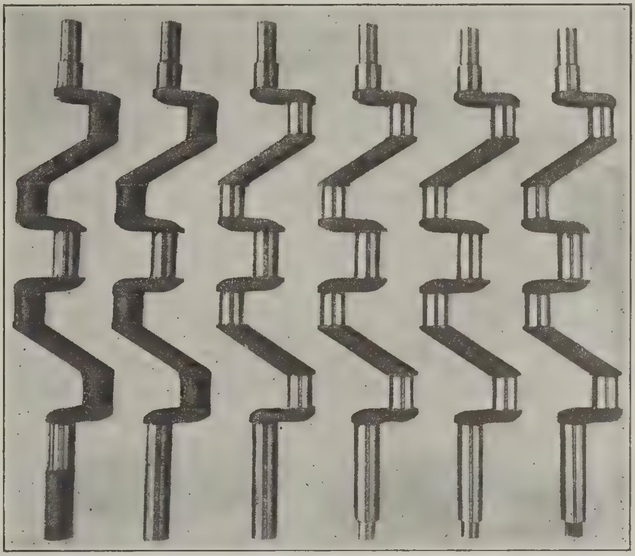

Fig. 2. Crankshaft requiring practically No Lathe Work in finishing

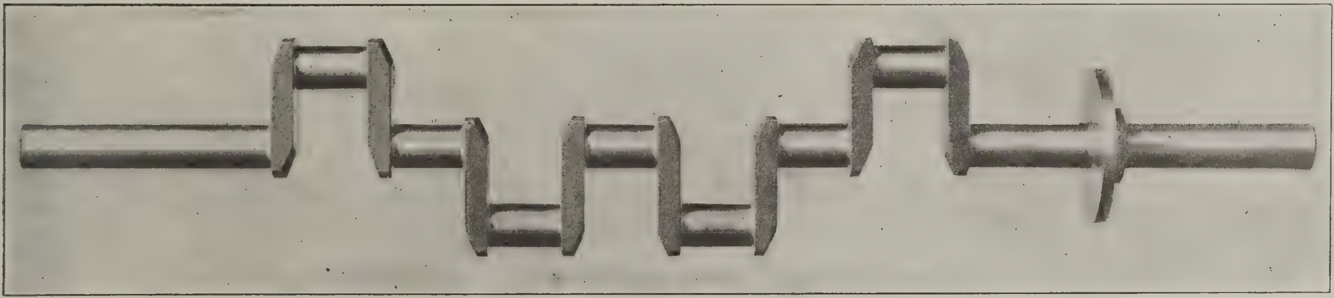

Fig. 1. A Crankshaft that is almost entirely finished in the Lathe

This loss is due to the fact that we turn closer than about 1/32 inch above the finished size. The word *about* is used because we lose by turning carefully. To require lathe work to be turned to thousandths today is like burning money for the fun of it. We are losing by allowing workmen to use any but the coarsest feeds that it is possible to use in each case. In some cases, it is even advisable to use the screw cutting gears. Feeds as coarse as four to the inch should be used in some cases, and feeds of six, eight and ten to the inch should be quite common. When the work is too frail to allow such coarse feeds to be taken with one cut, a second, or even three cuts should be made at a faster cutting speed; for, while it is true that very coarse and imperfect turning will require longer to grind than close, careful turning, the combination of coarse, cheap turning with grinding will produce cylindrical work

*Abstract of paper by Mr. C. H. Norton, of the Norton Grinder Co., Worcester, Mass., to be presented before the American Society of Mechanical Engineers, December, 1912.

†For additional information on grinding, see "Commercial Grinding," by F. B. Jacobs, in the October issue of MACHINERY, and other articles there referred to.

more efficiently. The modern grinding machine will remove metal most efficiently when that metal is in the form of coarse screw threads. High ridges do not increase the cost of production, and we lose money when workmen are allowed to caliper cylindrical work on the tops of the ridges, as nearly all of them do. This accounts for the misunderstanding about coarse turning and the allowance for grinding. Calipering on the tops of the ridges makes it necessary to turn with a relatively fine feed to enable clean grinding to be done. To avoid this, some workmen use a broad nose tool with the coarse feed, which necessitates the use of a slower cutting speed, because more metal is removed than with a pointed or grooved cutting tool. Ridges left by a more pointed tool do not increase the cost of producing that work, but decrease it.

We lose money by allowing workmen to measure roughed work elsewhere than at the end. Hours are wasted in calipering at several points and then resetting, and again turning the portions that have been put out by spring or tool wear, to secure straight work. It is very simple to feed a slight distance at the end of the work by hand, where the calipering can be done correctly, however coarse the power feed may be later on, or however high the ridges. The fact is overlooked that the modern grinding machine was designed to do all of the straightening and all of the sizing, regardless of what the errors of roughing may be. It is also forgotten, or has never been known, that the art of producing cylindrical work has progressed beyond that stage where it was necessary for the lathe to do its best before the grinding machine assumed the work of refinement.

The modern grinding machine is actually a correcting machine. The roughing can be rough, and roughness does not mean an approximate refinement. It is easy to figure the saving in time of turning a piece of work 6 inches in diameter by 6 feet long, when the last cut before grinding is made with a feed of six per inch, instead of thirty-two per inch, which is common. When it is considered that the grinding machine will grind this six per inch work to the finish size, in less time than is required to file thirty-two per inch work, we see the great possibilities for reducing the cost of producing work with the lathe, if combined with a modern grinding machine. In some cases money is lost by roughing at all in the lathe. Efficient production of cylindrical work is usually accomplished by first roughing in the lathe, but there are cases when the difference in favor of grinding without any roughing in the lathe is very great. The most important study for those who would secure efficient production of cylindrical work is the roughing of that work. It is here that we find the greatest possibilities for saving. If all would make a careful study of the roughing preparatory to grinding, instead of trying to improve upon the methods of grinding advocated by grinding machine makers, the result would be a more efficient production of cylindrical work and a clearer view of the real reasons why the grinding machine maker advocates certain methods. The reason why the modern heavy grinding machine was introduced would also be better understood.

At a works where large numbers of cylindrical pieces 1⅛ inch in diameter and about 10 to 11 inches long are manufactured, five minutes was required to turn about 1/16 inch from the diameter of each piece with a high-speed steel tool, the work being revolved as rapidly as the tool would stand. The plan was to turn close to the finish diameter, and care was taken to secure work that was smooth, straight, and round, so that time might be saved when grinding. They considered the grinding expensive and thought that this expense must necessarily be added to the cost of turning. The grinding in this case took one minute. The total time for producing these pieces was six minutes. A change was made in the shape of the tool point, and the size limit for turning, increased. The traverse feed was also increased, the cutting speed remaining unchanged. Each piece of work was now turned in one minute, while the grinding time was doubled so that it took two minutes. The saving of time resulting from the change was three minutes, or one-half of the original time.

Some idea of the time lost by allowing lathe work to be turned straight, smooth, and close to size, before grinding, may be obtained from the following illustration of actual work on some forgings about 4 feet 6 inches long. The turned portion had to be brought to a finish of 2 inches plus or minus 0.0005 inch in diameter, and 3 feet long. The lathe operator turned these pieces in the same manner that the majority of operators are now turning such work, *viz.*, as such work was turned before grinding machines were introduced, except that 0.010 inch was left on the diameter for grinding. The turning required two cuts, as there was more than ⅛ inch to remove and the work was somewhat frail, as well as irregular. The first cut was considered a very coarse heavy cut by the workman. The second was like the last cut in the majority of shops, *viz.*, it gave what the lathe men and most foremen call "a good job." When ready for grinding, the time consumed by turning was 25½ minutes. This appears to be too slow, but the forging was so slim that it would allow little, if any, increase in each roughing cut, and the lathe was an old-time low-power, frail machine. The grinding time on this job was three minutes, making a total of 28½ minutes.

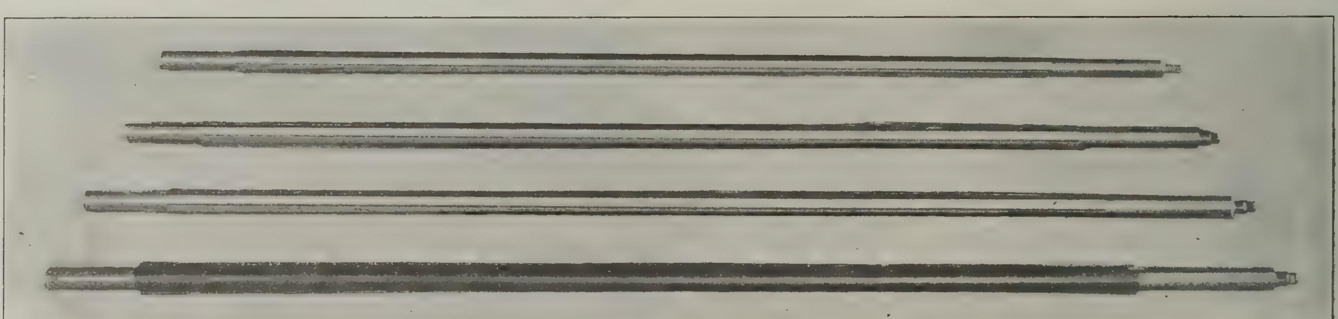

Fig. 8. Work Too Thin to be turned efficiently—finished entirely by grinding

Now note what was accomplished with the same low-power lathe and the same work, when tradition was ignored and the work made ready for grinding in the proper way. Two roughing cuts were taken, because the lathe was not powerful and the work was frail. The feed was ten per inch, cutting deep grooves; the time complete ready for grinding was nine minutes. The work was not straight, and was what many lathe men would style "a very poor job." The grinding time occupied to bring the work to exact limits was nine minutes, or three times longer than with the more careful turning, and the total time eighteen minutes, a saving of 10½ minutes on each forging. An attempt to rough this work with one cut instead of two resulted in a loss of two minutes. A modern, high-power lathe would have carried the same feed and depth of cut at a higher cutting speed, with a still further reduction of time. This shows us what may be accomplished with our weak low-power lathes. To install high-power lathes and continue to turn just as smoothly and accurately as of old, simply allowing a few thousandths for grinding, would seem the height of wastefulness. Whether high-power lathes, or old low-power lathes are used, mechanical industries are losing an enormous sum each year because of the lack of understanding of the efficient production of cylindrical work —the proper combination, in each individual case, of rough turning and grinding.

Some idea of what we are losing by not wearing our "thinking cap" is shown by the following: Some plain shafts, 1 5/16 inch in diameter and 62 inches long, were to be made

to ordinary limits of size and finish. Tests were made to determine whether it was better to turn these first, or to grind direct from the rough bars. The turning required six minutes ready for finish grinding, while to grind off the same amount as was turned required nine minutes. A number of mechanics, without thinking, pronounced it cheaper to turn these shafts first. But in this case, after turning in six minutes, each shaft required straightening before grinding; this consumed ten minutes on each shaft, totaling sixteen minutes. When the roughing was done by grinding instead of turning, no straightening was necessary, and the roughing cut was taken in nine minutes. In this case, therefore, the turning was actually lost. There may be similar cases where the shafts will require some little straightening, even if roughed by grinding, so that each case should be investigated, instead of making a rule that all must or must not be turned first. Usually, however, no straightening is necessary when roughing is done by grinding.

Money is being lost because the majority of designers have not kept pace with the development along these lines. A

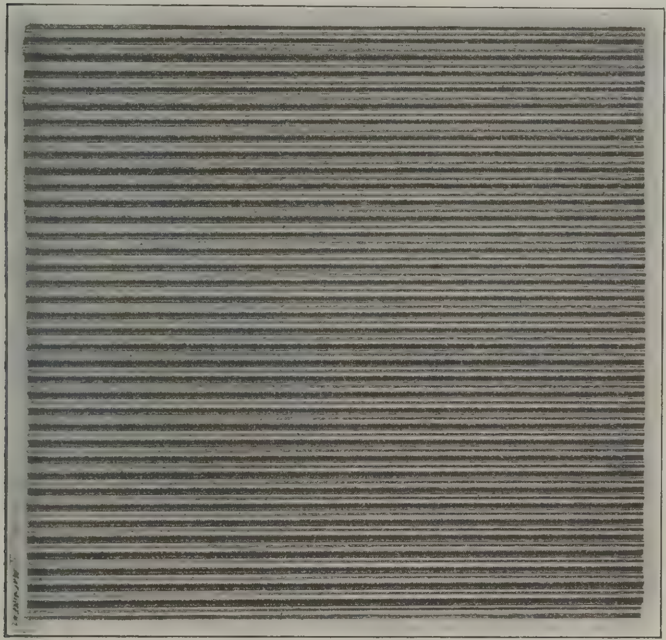

Fig. 4. Thirty-seven Slim Shafts ground direct from Rough

well-known runabout motor car has a crankshaft, which, if made about one inch longer over-all, could have been produced for 50 cents less on each crank. When it is considered that about 30,000 of these cranks have been made, representing a possible saving of $15,000, we see the importance of the combination of lathe and grinding work.

Fig. 1 shows a design of crankshaft that is expensive to machine, as it requires careful finished lathe work. It will be seen that this shaft has a flange that must be finished complete by the lathe. Aside from the flange, the design necessitates lathe finishing of the majority of the work. Grinding is a small part of the whole.

Fig. 2 shows a design that requires no lathe work whatever, there being clearance for the sides of the grinding wheel at all points. The illustration shows the six operations to complete the shaft after cutting off the ends and centering. These shafts are finished to the usual limits, direct from the drop-forging, by grinding. The net labor cost for cutting off ends, centering, machining complete with one keyway, and cutting the thread, so that the shaft is ready for the automobile, is 55 cents. The cost for grinding wheel is 2½ cents for each shaft, and the cost for the diamond to true and shape the wheel is 2 cents.

Another feature affecting the cost of production is the matter of shoulders. This is overlooked by many designers, and practically all draftsmen, who show sharp corners at the junction with the cylindrical portion. It is so easy to draw two sharp lines that cross each other and form a sharp corner. The fact that it costs less to provide room for the shoulder fillet on the other member than to make a sharp corner in the cylindrical member is lost sight of. This, no doubt, is the result of the experience of the past, when there were no powerful grinding machines to locate and form such shoulders cheaper than the lathe could. Shoulders made with the grinding wheel require a slight fillet.

When numbers of duplicate pieces are to be produced and a small fillet is allowed, not only can the cylindrical portion be roughed with the lathe and not at all refined, but the shoulders can also be roughed, because the grinding machine, when required, is provided with a locating bar. By the use of this bar, the exact location of all shoulders can be secured by grinding, without necessitating any measuring. At the same time, the cylindrical portion can be ground with the same grinding wheel. The roughing in the lathe can be done with the same tool that roughs the cylindrical portion because the lathe, in this case, is not required to give the shoulder any particular shape. When it is found best to locate and finish shoulders with the lathe, because there is no locating bar for the grinding machine, it should not be necessary to neck in at the shoulders for grinding. This is an old and out-of-date notion, for, with a shoulder cut sharp by the lathe tool, the grinding does not materially change the corner. A more efficient method, when no locating bar is at hand, is to rough the work in the lathe, leaving the shoulders about 1/32 inch long and of whatever angle the rough-turning tool may form. Next grind the cylindrical portion and, at the same time, cut out the angle at the shoulder with the grinding wheel. The work should then go to a lathe where a more skillful operator can locate the shoulders accurately; if a sharp corner is really necessary, it can then be made.

Fig. 3 shows work that is so slim that turning the main portion is out of the question, if it is to be produced efficiently. The main or center portion should be ground direct without turning. Fig. 4 shows thirty-seven slim shafts ground direct from the black stock. To turn them first would be a waste of time. They were 30 inches long by 11/16 inch in diameter in the rough. They were ground to 0.625 inch plus or minus 0.0005 inch; the work was handled twice and ground complete in seventeen minutes for each piece. The stock was tool steel. A lot of sixty countershafts of 35-point carbon steel, finish size 2 3/16 inches plus or minus 0.0005 inch by 66 inches long, were turned eight pitch, leaving about 1/32 inch for grinding. They were ground complete in thirty-five minutes each. The number of cubic inches of steel ground off was 278; 20.7 cubic inches of steel being removed for every cubic inch of wheel wear. The total wheel cost for sixty shafts was 38 cents, and the total cost for power, 35 cents. The type of wheel used was 24-combination grade L, alundum. The radial depth of cut when roughing was 0.001 inch and when finishing 0.0005 inch. The surface speed of work when roughing was 42 feet per minute, and finishing 35 feet per minute. The table traverse for roughing was 11¼ feet per minute and for finishing 10 feet per minute.

To produce cylindrical work efficiently we must make a study of everything that affects the problem in each individual case, instead of following tradition, which is costing us thousands of dollars every year. Lathe builders are offering some very efficient roughing lathes, but are we roughing with them? In most cases, we are not. The real roughing lathe needs a good system of multiple steadyrests to enable it to take rapid and deep coarse cuts. Will someone come forward with such a system of steadyrests? Instead of our lathe departments and grinding departments being separate, there should be one department for cylindrical work under one foreman. This would check the tendency of the lathe department to treat their work as a finished product, and the tendency of the grinding department to insist upon close careful turning in order to make a better showing on the grinding time, regardless of the real cost of production. There is much yet to be learned about the preparation of cylindrical work for grinding, as no two pieces of work require the same lathe treatment. There is also a great need for thinking men as foremen and operators. Such men can effect great savings by working out the best combination of turning and grinding for each class of cylindrical work.

NEW SHOP OF THE CINCINNATI GEAR CO.

The Cincinnati Gear Co. is now located in its new shop at 1825–1833 Reading Road, Cincinnati, Ohio. A good idea of the modern construction and equipment of this shop may be obtained from reference to Figs. 1, 2, and 3. The building has been provided with an exceptional window area which affords an ample amount of daylight, so that all machines may be operated without artificial illumination.

This company started in business in a small way, two years ago, and has grown rapidly. A specialty is made of rawhide and bevel gears, and an idea of the quantity of work turned out may be gathered from the fact that fifteen bevel gear machines are kept in operation all the time. All kinds of bevel gears—including those of fractional pitch—are cut without the use of form cutters or templets, planer generators being used exclusively.

MACHINE TOOL EXHIBIT AT NATIONAL AUTOMOBILE SHOW

A new feature of much interest to the machine tool building industry will be added to the thirteenth National Automobile Show, to be held in Madison Square Garden and Grand Central Palace, New York, January 11 to 25. A machine tool exhibit is planned for the Part II period, or second week, beginning January 20, which is devoted exclusively to commercial vehicles. The proposed exhibit has received the approval of President E. P. Bullard, Jr., of the National Machine Tool Builders' Association and of its executive committee.

Fig. 2. Corner of the Lathe Shop showing Liberal Window Space

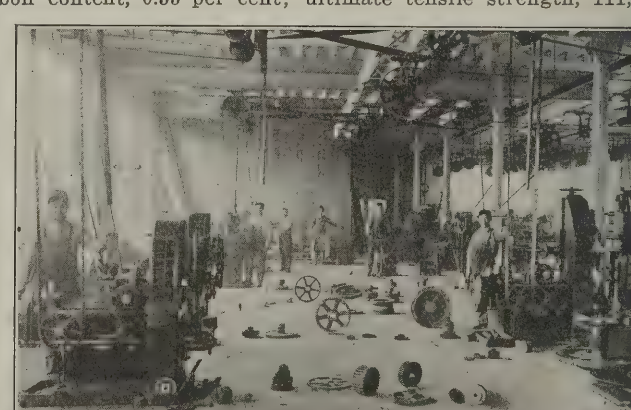

Fig. 3. The Spur Gear Shop and Some Samples of Work

The members of the Society of Automobile Engineers, many of whom will attend the show for the entire two weeks, have expressed themselves as being in favor of a display of machine tools and accessories used largely in the manufacture of motor cars. The time is ideal for the machine tool builders supplying the automobile trade to meet the men personally who are vitally interested in their product. Automobile factories throughout the country are constantly increasing their machine tool equipment, and their engineers will welcome the opportunity to see the latest developments.

The exhibit of cars in the second week of the show has not attracted the general public in large crowds, but chiefly business men, manufacturers and mechanical engineers concerned with the problems of transportation and in the development of motor trucks and delivery cars. The educational value of the proposed exhibit of machine tools to these classes is of no little importance. The intention of the management is to make the display of machine tools an annual feature of future shows.

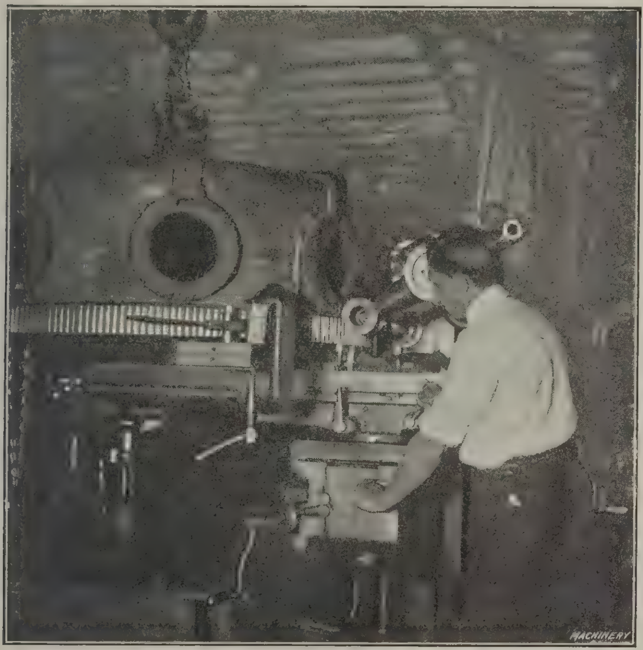
Tests made at Watertown Arsenal some time ago, which strikingly demonstrated the truth of Wöhler's law that the endurance of steel decreases rapidly with increases of stress above a certain percentage of the elastic limit, were cited in an article "The Factor of Safety" appearing in the first number of *The Travelers Standard*. Wöhler, a German railway engineer who was the first to scientifically investigate factors of safety, had observed that car axles often break after having run a certain number of miles although when new their strength was several times that required to carry the load, and from this fact was led to investigate the phenomena of fatigue of metals. The Watertown tests were made on steel specimens having the following characteristics: Carbon content, 0.55 per cent; ultimate tensile strength, 111,200 pounds per square inch; elongation, 12 per cent; reduction of area, 33 per cent; elastic limit 59,000 pounds per square inch. Under repeated alternate extension and compression stresses a specimen under maximum stress of 30,000 pounds per square inch withstood 76,326,240 repetitions without breaking; under 35,000 pounds a specimen broke at 900,720 repetitions; under 40,000 pounds, at 455,000; under 45,000 pounds, at 166,240; under 50,000 pounds, at 93,160; and under 60,000 pounds, at 12,400.

AN UNUSUAL GEAR CUTTING JOB

An unusual job of gear cutting was recently performed in the shop of William Ruwell, 719-21 Noble St., Philadelphia, Pa., and is believed to be one of the largest pieces of gear cutting which has ever been done on a No. 4 milling machine. The work consisted of an iron casting 56 inches in diameter which had a four pitch gear cut on its outside circumference. The gear face was 3 inches in width, the total width of the casting 24 inches, and its weight about 2680 pounds.

This gear was cut on a No. 4 Cincinnati universal high-power milling machine. The casting was supported by a ball bearing placed in the center at the top and a triple rope and block tackle was used to raise it into position. The weight of the casting was counterbalanced, the counterweight being located at a point where it could not interfere with the work. This arrangement worked so well that it was estimated that the casting was raised by a pull not exceeding ten pounds.



An Unusual Job for a No. 4 Milling Machine

The regular universal dividing head was moved to the extreme left end of the milling machine table; the spindle of the head was then placed in a vertical position and an arbor made to fit the hole in the casting. The other end of the arbor was located in the dividing head. The casting was now lowered onto this arbor and a stocking cut taken all the way around. The casting was then examined to see that this stocking cut gave accurate results, after which the worm-wheel of the dividing head was thrown out, and with the casting still mounted on the dividing head, a pawl was attached to the table of the milling machine. This pawl was now used for indexing the work, the C-clamp shown in the illustration being used to hold the casting securely in position. Although this work is considerably beyond the range usually covered by a No. 4 milling machine, the job was turned out with satisfactory results.

IMPORTANT PATENT DECISION AFFECTING TRUST AGREEMENTS

The United States Supreme Court, on November 18, affirmed the opinion of the Federal District Court of Maryland that the Standard Sanitary Mfg. Co., and forty-nine other defendants, constituting the so-called "bath-tub trust" are not, under the patent laws, warranted in making the license agreement under which they have been doing business. Under this license agreement, the various manufacturers of bath-tubs were allowed to use a patented device in their manufacturing processes, but only on condition that they abided by an attached price list, would not sell to jobbers who bought from independents, would not sell in a certain territory, and would not sell "seconds." The court held that it is illegal for the manufacturer of a patented article to fix the price at which articles manufactured by it must be sold at retail, and thus laid down the broad principle that there can be no monopoly in the unpatented product of a patented machine without the violation of the anti-trust law. Justice McKenna delivered this as the unanimous opinion of the court.

The Supreme Court in this decision refuses to extend the doctrine of the Dick mimeograph case to the unpatented product of a patented machine. The defendants in the bath-tub case owning patents on machines used in the manufacture of enameled ware attempted to fix prices and destroy competition in an unpatented product, but their conduct was held to be illegal. This decision, together with that of the Dick mimeograph case, in which it was held that the purchaser of a patented device could be compelled to buy from the patentee all the supplies used on that particular machine, are probably the two most important decisions in patent cases in a number of years.

HEAVY THIRTY-SIX-INCH LATHE JOB IN A PITTSBURG STEEL PLANT

An exceptional lathe operation which was recently performed in one of the large steel plants in the Pittsburg district is illustrated herewith. The work is a 3½ per cent nickel steel shaft, which was turned from a forging 25 feet 5 inches in length by 22 inches in diameter, which weighed 33,000 pounds. When finished, the maximum diameter was 20 inches and the weight 28,000 pounds. The engine lathe used for this purpose is of the regular 36-inch triple-geared type manufactured by the Boye & Emmes Machine Tool Co., successors to Schumacher & Boye, Cincinnati, Ohio. The ability to deal with such a job, which is necessarily a most severe test, certainly speaks well for the capacity of the lathe on which the work was performed.

Turning an exceptionally Large Nickel Steel Shaft on a 36-inch Boye & Emmes Triple-geared Engine Lathe

SLOTS IN SCREW HEADS—WIDTH OF FLAT ON SHANKS OF TOOLS

For ordinary fillister-head screws, where the diameter of the head is made in proportion to the diameter of the body of the screw, the width of the screw slot ought to be made according to the standard approved by the American Society of Mechanical Engineers in May, 1907. According to this standard, the width of the slot is figured from the formula $D = 0.173A + 0.015$ inch, in which D equals the width of the slot for the screw-driver and A equals the diameter of the body of the screw itself. When the screw heads are made especially large in proportion to the body of the screw, however, as shown in the illustration at the top of the accompanying table, this formula is not adaptable, as the screw slots would be entirely too narrow for the size of the head, and, in that case, it is better to base the width of the slot for the screw-driver on the diameter of the head rather than on the body diameter of the screw. In this case the width of the screw-driver slot is calculated from the formula $D = B \times 0.090$, in which D equals the width of the screw-driver slot and B the diameter of the head of the screw. This formula gives good proportions for average conditions, although, of course, judgment must be used in drawing the line between the conditions when the regular A. S. M. E. formula ought to be used and when the head is large enough to call for the use of the present formula. A table is given in which the width of the screw-driver slot is calculated for different diameters of head according to this formula.

1 1/4	0.469	...	.....

The width of the flat for set-screws on round shanks of tools may not seem to be of great importance, but, nevertheless, it is advisable to have a standard for this. The accompanying table gives, therefore, the width of the flat A for a number of different diameters B figured from the formula $A = \frac{3}{8} B$. If the flat is milled to this width, the appearance of the tool shanks will be satisfactory, and by using a standard, uniformity is assured.

Tools with a square milled on the shanks often present a bad looking appearance by having sharp corners. This often produces burrs on the square itself, which prevent the tools from entering the socket or wrench in conjunction witn which they are used, and—what is still worse—is often the cause of bruised and cut hands. A well-proportioned square having a good round corner is obtained if the width across the flats is made ¾ times the diameter of the shank. A.

LAUNCHING OF THE NEW YORK

The ninth U. S. dreadnaught *New York* was launched at the Brooklyn Navy Yard October 30. This battleship is a sister ship to the *Texas*, building at Newport News by the Newport News Shipbuilding & Drydock Co., and is the largest yet launched. Her keel was laid in September, 1911, and when launched the construction was about sixty per cent completed; the hull at launching weighed over 9000 tons. About 25,000 pounds of special grease was used to lubricate the launching ways. These ways consist of two wooden tracks, each about four feet wide and thirty feet apart upon which the vessel rests at launching, being supported in a cradle or sliding ways built to conform to the hull. The spectacular "sawing off" of the sliding ways to release the vessel was made obsolete by a double trigger device, located in the launching ways amidship, and operated by two hydraulic plungers. The vessel had been wedged up onto the launching ways and was held only by the triggers when the signal was given. The turn of a valve released the liquid in the cylinders, and the weight of the vessel pressed the triggers down out of the way, thus freeing her to slide into the water. The mechanism worked perfectly and will be used hereafter; it insures the safety of the men, and enables the time of release to be fixed to the fraction of a minute.

The *New York* is the largest and most formidable battleship in the world, the mean displacement being 27,000 tons; the length on water line, 565 feet; breadth at water line, 95 feet; mean drafts, 28 feet 6 inches. The propelling machinery is triple expansion reciprocating engines of 28,100 H. P. driving two propellers. The main battery comprises ten fourteen-inch rifles and four submerged twenty-one-inch torpedo tubes; and the secondary battery, twenty-one five-inch rapid fire guns, and smaller pieces. The cost of the fourteen-inch gun and mount is $62,000 for the gun and $50,000 for the mount. The life of a gun before relining is necessary is 225 rounds. The range at fifteen degrees elevation is over twelve miles, and the penetration of face-hardened armor at six miles is sixteen inches. The cost of a round of ammunition is $600. The total cost of the vessel, hull and machinery exclusive of armor and guns is about $6,000,000.

* * *

PERSONALS

Robert Cary has resigned his connection with the Gisholt Machine Co., Warren, Pa., and taken a position as superintendent of the J. N. Lapointe Co., New London, Conn.

H. S. Kartscher has left the designing department of the Pratt & Whitney Co., Hartford, Conn., to take the position of chief draftsman of the Rivett Lathe & Grinder Co., Brighton, Boston, Mass.

M. O. Frenier, mechanical engineer, formerly with the engineering department of the Knox Automobile Co. of Springfield, Mass., has opened an engineering office at 168 Bridge St., Springfield, Mass.

J. E. Brennan, who for several years held the position of assistant superintendent of the Remington Arms–Union Metallic Cartridge Co., at the works in Ilion, N. Y., has been appointed superintendent of the works.

A. J. Jones, formerly with the Lodge & Shipley Machine Tool Co., Cincinnati, Ohio, has been made secretary and manager of the Acme Machine Tool Co., of Cincinnati, manufacturer of turret lathes and screw machines.

Walter G. Lamont, late with Elliott & Fisher Co., Harrisburg, Pa., manufacturer of billing machines, has taken the position of mechanical engineer with the Simplex Non-Refillable Seal & Stopper Co., at Baltimore, Md.

Henry K. Swinscoe has resigned the position of assistant superintendent of the South Works of the American Steel & Wire Co., Worcester, Mass., to enter the employ of the Morgan Spring Co., of Worcester, as superintendent.

Clifford F. Kern, formerly president of the Kern Machine Tool Co., Hamilton, Ohio, has disposed of his interest in that company and purchased the Von Wyck Machine Tool Co. of Cincinnati, manufacturer of 15-inch engine lathes.

Fred R. Jochmus, who for several years has been assistant foreman in the machine shop department of the Remington Arms–Union Metallic Cartridge Co., at Ilion, N. Y., has been appointed foreman of the machine shop department.

F. B. Jacobs, for several years in the employ of the Carborundum Co., Niagara Falls, N. Y., in various capacities, and

a frequent contributor to MACHINERY, has resigned from his position as salesman in the company's Philadelphia office.

Edward K. Hammond of Chicago, a frequent contributor to the technical press, has joined the editorial staff of MACHINERY. Mr. Hammond is a graduate of Armour Institute of Technology, and has had practical shop and editorial experience.

Corneil Ridderhof, formerly treasurer and manager of the Wilmarth & Morman Co., Grand Rapids, Mich., and an occasional contributor to MACHINERY, has taken a position as assistant manager of the Western Gas Engine Corporation, Los Angeles, Cal.

Charles A. Schaefer, formerly general foreman of Schumacher & Boye, and for fourteen years with that company, has taken a position as superintendent of the John B. Morris Machine Tool Co., Cincinnati, O., manufacturer of lathes and radial drills.

Frank J. Lapointe, secretary of the J. N. Lapointe Co., who has been acting as superintendent of the works, will now give his whole attention to the engineering department of said concern, as Mr. Robert Cary, formerly of the Gisholt Machine Co., Warren, Pa., is now the superintendent.

Walter B. Snow, publicity engineer, 170 Summer St., Boston, has recently increased his staff by the addition of Mr. Fred R. Lufkin, formerly of the instruction staff in electrical engineering of the Massachusetts Institute of Technology, and late assistant superintendent of lighting and wires of Brookline, Mass.

Joseph Wolf, formerly of the Hisey-Wolf Machine Co., Cincinnati, Ohio, has become interested in the Cincinnati Electrical Tool Co., and has been made vice-president and general manager. The company makes portable electric drills and grinders and Mr. Wolf will take entire charge of the management of the business.

E. P. Bullard, Jr., president of the Bullard Machine Tool Co., delivered an address Tuesday evening, November 26, before the Cleveland Engineering Society in Cleveland, Ohio, on the subject, "A New Era in Machine Design," in which the basic principles of the design and construction of machines which will fully meet the new requirements of the present-day manufacturer, were discussed.

E. J. Kearney, president of the Kearney & Trecker Co., Milwaukee, Wis., who was very ill with pneumonia in Boston, at the time of the recent National Machine Tool Builders' Association's annual convention in New York, has recovered, after having been confined to the hospital for five weeks. Mr. Kearney is gradually regaining his strength, and recently passed through New York on his way home with Mrs. Kearney, traveling by easy stages.

Henry Hess has resigned as president of the Hess-Bright Mfg. Co. and has sold all of his holdings in that company. It is understood that no change in the policies of the company is contemplated. Mr. Hess became interested in ball bearings while general director of the German Niles Tool Works. The Deutsche Waffen-und Munitions Fabriken ball bearings had just become famous through their use in the German Mercedes automobile in the winter of 1901. Up to this time all the early types of ball bearings had been failures as applied to automobiles. Owing to its novel mechanical features and high efficiency, the German Mercedes car made a great sensation, and the general adoption of ball bearings in automobiles soon followed. Armed with the American rights of the DWF ball bearings, Mr. Hess came to this country and in 1904 formed the Hess-Bright Mfg. Co. The company started with a small one-room office, and grew until today it owns a new factory and thirteen acres of land at Front St. and Erie Ave., Philadelphia. The history of the company is, in part, Mr. Hess's history. At first the bearings were used only in automobiles. Since then, however, the field has broadened, and Mr. Hess has made applications of the bearings in many other types of machines in the industrial world, especially adapting them for use at points where plain bearings would not stand up, as where high speed is necessary. Mr. Hess has contributed largely to the technical literature of ball bearings and is looked upon as one of the foremost authorities in America on the subject. He was judge of the mechanical exhibit at the St. Louis Exposition; he is a member of the council of the American Society of Mechanical Engineers, a former president of the Society of Automobile Engineers, and chairman of the Philadelphia Branch, president of the Engineers Club of Philadelphia and a member of the fair practice committee of the Motor and Accessories Manufacturers Association.

COMING EVENTS

December 3-6.—Annual meeting of the American Society of Mechanical Engineers in New York. Calvin W. Rice, secretary, 29 W. 39th St., New York.

December 5-7.—Sixth annual convention of the National Society for the Promotion of Industrial Education in Philadelphia, Pa. Headquarters, Hotel Walton. C. A. Prosser, secretary, 105 East 22d St., New York.

January 11-18.—National Association of Automobile Manufacturers show of pleasure vehicles at Madison Square Garden, New York. M. L. Downs, secretary, 7 East 42d St., New York.

January 20-25.—National Association of Automobile Manufacturers show of auto-truck and delivery cars at Grand Central Palace, New York. M. L. Downs, secretary, 7 East 42d St., New York.

NEW BOOKS AND PAMPHLETS

ROAD LEGISLATION AND ADMINISTRATION IN IOWA. By John E. Brindley. 112 pages, 8¾ by 5¾ inches. Three tables of information on road legislation and administration. Published by the Engineering Experiment Station, Iowa State College of Agriculture and Mechanical Arts, Ames, Iowa, as Bulletin No. 28.

TABLE OF ANGLES OBTAINABLE ON THE DIVIDING HEAD. Prepared and published by C. W. Ripsch and P. W. Hirsch, 113 Hawthorn St., Dayton, O. Price 25 cents.

These tables were prepared to meet the needs of machinists and toolmakers who are required to find angles on the dividing head of the milling machine quickly. The tables cover all the angles obtainable by simple indexing, using the plates furnished with the machine and an additional plate containing ninety holes, and are calculated to the nearest second.

THE A B C OF THE DIFFERENTIAL CALCULUS. By William Dyson Wansbrough. 148 pages, 7⅜ by 5⅛ inches. 30 illustrations. Published by D. Van Nostrand Co., New York. Price $1.50.

The object of this little book, which is clearly expressed by the title, is to present the essential details of the differential calculus in as concise and readily understandable a manner as possible. The present is the third edition, and is practically unchanged. The book can be recommended to those who wish to study the calculus at home. The subject is presented simply and progressively; the language often is unmathematical and the examples are drawn from everyday practice.

EMERY AND THE EMERY INDUSTRY. By A. Haenig. 103 pages, 7½ by 5 inches. 45 illustrations. Published by D. Van Nostrand Co., New York. Price $2.50.

The development of competition in the machinery industry has fully justified the expression that "time is money." This condition has led to the development of many forms of machinery that not only assist the workman in carrying out certain operations, but in many cases, actually do away with a large amount of hand work. Among such improvements, the substitution of emery wheels for the old type of grindstone, or for the file, has found wide application. In the present text, the author presents to both the engineer and layman, a general discussion of the subject of emery and the emery industries, treating of the raw materials, the finished wheels, and machines used to drive them, in the classes of work where they find application.

THE MECHANICAL WORLD POCKET DIARY AND YEAR BOOK FOR 1913. 330 pages, 6¼ by 4¼ inches. 71 illustrations. Published by Emmott & Co., Ltd., 65 King St., Manchester, England.

The latest edition of this annual contains a variety of useful information on mechanical engineering which is presented in convenient form for reference. The opening chapters deal with subjects pertaining to power installations and cover steam, gas and oil units. Following this section comes information on power transmission with useful tables on the standard dimensions of equipment used for this purpose. A considerable amount of useful information on machine shop practice is also presented chiefly in tabular form. In addition, the book contains a number of tables on the characteristics of engineering materials and also tables of mathematical constants. Considering the low publisher's price—six pence— this book is a remarkably cheap and valuable handbook.

FORGING, STAMPING AND GENERAL SMITHING. By Benjamin Saunders. 428 pages, 8¾ by 5¾ inches. 728 illustrations. Published by Spon & Chamberlain, 123 Liberty St., New York. Price $7.50, net.

The information presented in this book will be found of value to foreman-blacksmiths, engineers and managers, and others concerned with the operation of blacksmith shops. The text includes matter on forging, stamping and general smithing, the methods in each case being freely illustrated and described in a concise and readily understood manner. The author is, himself, a practical foreman-blacksmith and has drawn his information from a wide experience with the subject upon which he writes. One of the points of particular value is that the time required to complete given operations is indicated in connection with the description of the method to be followed. The time and other data presented have been carefully verified by the writer; the work, therefore, may be taken as a guide by those who are looking into the efficiency of blacksmith shop operation.

GASOLINE ENGINES; THEIR OPERATION, USE AND CARE. By A. Hyatt Verrill. 275 pages, 7½ by 5¼ inches. 152 illustrations. Published by Norman W. Henley & Son, New York. Price $1.50.

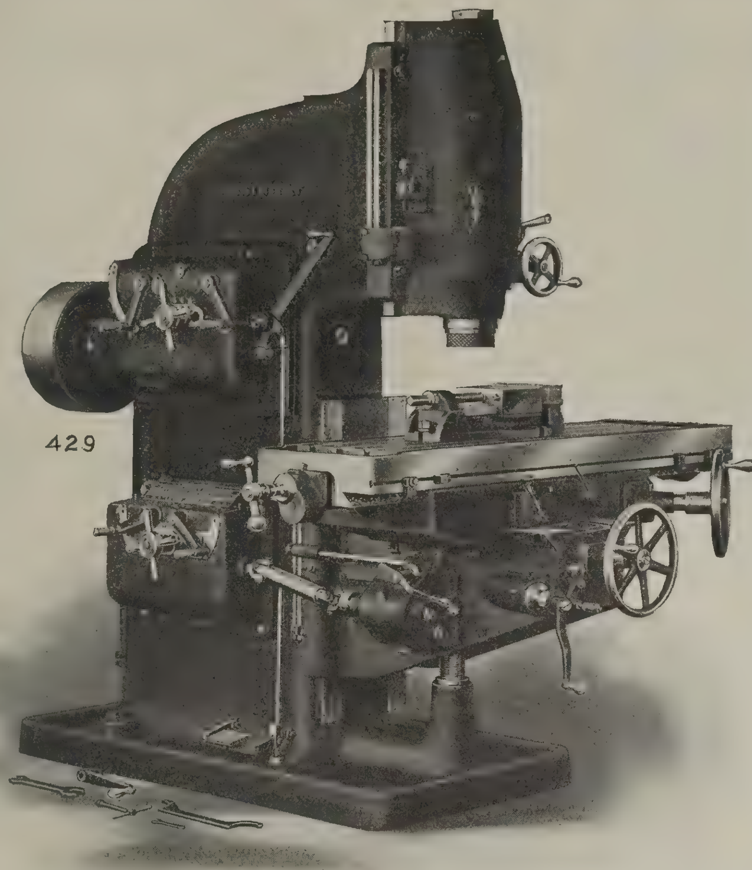
The wide application of gasoline engines to motor-driven vehicles and to a variety of classes of stationary service, has created a need for a book dealing with the methods of operating and caring for this type of equipment. The subject is one which affords an opportunity for highly technical treatment, but such a text would be of little value to the many users of gasoline engines who are non-technical men. It is for the use of such readers that the present volume has been written. The text gives all necessary information concerning the operation and care of gasoline engines in simple language, and the use of technical terms has been avoided as far as possible. There are certain cases, however, where technical terms have to be used, as for instance, in ordering new parts, but to make these clear, a glossary has been included which gives the meaning of all the technical terms used.

SOFT SOLDERING, HARD SOLDERING AND BRAZING. By James F. Hobart. 190 pages, 7 by 4¾ inches. 62 illustrations. Published by D. Van Nostrand Co., New York. Price $1, net.

Some mechanics believe that the operations of soldering and brazing are comparatively simple, requiring no special degree of skill or experience on the part of the workman. As a matter of fact they involve a wide range of manipulations, and frequently demand experienced workmanship of a high order. At the same time, so many mechanics are accustomed to performing soldering operations with tools and appliances which might be greatly improved upon, that the author has been led to offer this book in the hope that it will serve as a practical aid to an improvement of methods. If such a purpose can be accomplished, the interests of both mechanics who seek advancement and employers who are awake to the importance of efficiency and economy, will be advanced by a careful study of this volume. The different phases of soldering and brazing are dealt with, the subject matter being based upon the author's experience in this work.

TOOTHED GEARING. By George T. White. 217 pages, 7⅜ by 4¾ inches. 136 illustrations. Published by D. Van Nostrand Co., New York. Price $1.25.

This book is presented by the author with the view of explaining simply the action of the principal forms of gear teeth. The two forms of tooth profile in most common use—the cycloidal and the involute—have been considered in detail, neither being strongly advocated in preference to the other. On cut gears, the involute curve is preferred to the cycloidal, and has almost entirely displaced it on such wheels. This change has gone so far that the involute form may very shortly become the generally accepted standard the world over for machine-cut teeth. The contents by chapter heads are: Kinematics; The Spur Wheel—Cycloidal Teeth; Annular Wheels—Cycloidal Teeth—; The Spur Wheel—Involute Teeth; Obliquity of Action, etc.; Pin Gearing; Non-Circular Wheels; Lobed Wheels; Helical Wheels; Bevel Wheels; Skew Bevel Wheels; Worm-Gearing; Oblique Worm and Wheel; Screw Wheels or Spiral Wheels; Strength of Teeth; Durability; Trains of Wheels; The Odontograph.



THE operator can change the direction of the table movement—longitudinal to cross and back again—by the two levers at the front of any Cincinnati Vertical Miller.

He always moves the levers in the direction he wants the table to go. There is no lever down under the table at the back of the knee for determining the direction or reversing. All levers are at the front with the operator.

It is easy to mill around the periphery of a rectangle because the changes in direction can be made without stopping. In fact, both longitudinal and cross feeds can be used in combination, when it is profitable to do so, which is the case on much work.

These things make the man's task easier, enable him to operate the machine quicker and produce more work.

And our Verticals are so rigidly constructed, that they can produce flat surfaces on such difficult pieces as the flanges of covers or gear cases, etc., and not leave an offset where the cut ends.

Send us your blueprints and we will show how this applies to your work.

How to Read a Drawing. By Vincent C. Getty. 64 pages, 9¾ by 6¾ inches. 61 illustrations. Published by J. B. Lippincott Co., Philadelphia and London. Price $1, net.

There is probably no study of more general use to the practical mechanic than the reading of drawings. No matter what class of work he is engaged upon there will be constant occasion for him to use drawings in carrying on his work. This knowledge can be readily acquired by the young mechanic without being well informed on engineering or other technical matters, as it is only necessary for him to be able to read English to enable him to acquire a working knowledge of mechanical drawings. In presenting this book, the author has endeavored to explain the methods of reading a drawing without the use of technical terms, but where it has been absolutely necessary to include such terms an explanation of them has been given. The main principles of drawing are thoroughly explained and sufficient examples are given to enable anyone to clearly understand a drawing which may be placed before him. This is a book which is particularly adapted to home study and should enable any mechanic to acquire knowledge upon a subject that will be of particular value to him.

Practical Mathematics. By Claude Irwin Palmer. Part I. Arithmetic With Applications; 139 pages, 7⅛ by 4¾ inches. 20 illustrations. Part II, Geometry with Applications; 149 pages, 7⅛ by 4¾ inches. 130 illustrations. Published by McGraw-Hill Book Co., 239 West 39th St., New York. Price 75 cents, net, per volume.

The subject of mathematics is one with which many mechanics are insufficiently acquainted, and the realization of this fact causes many to attempt to remedy the deficiency by attending evening classes. During the past eight years Mr. Palmer has taught evening classes in mathematics comprising a total of over 500 men, and has prepared the text to meet the requirements of such students. In all cases, the subject matter has been made as practical as possible in order that its application to actual problems which the students will subsequently encounter in the shop, may be made as easy as possible. The series will be completed by two other volumes covering the subjects of algebra and trigonometry, and it appears that the complete text should meet a need in presenting mathematical subjects in evening classes, continuation schools, etc., which are primarily intended for the education of practical men of somewhat advanced years.

The Theory of Engineering Drawing. By Alphonse A. Adler. 312 pages, 9 by 6⅛ inches. 273 illustrations. Published by D. Van Nostrand Co., New York. Price $2.

The subject matter of this volume is largely the same as that of many other treatises on descriptive geometry but the author has given it the title "Theory of Engineering Drawing," believing that this indicates the ultimate purpose of the book in a better way. The text was written with the purpose of correcting certain weaknesses in the presentation of the subject of descriptive geometry, and emphasizes the fact that the student is concerned with the representation on a plane of objects in space or three dimensions. Although analysis is important as affecting primary purposes, the development of methods for representation and interpretation of the resulting drawings cannot be regarded as an end in itself. The number of fundamental principles treated in the text has been reduced to a minimum; indeed it will be found that the entire text is based on the problem of finding the piercing point of a given line on a given surface, together with a few additional problems. The author believes that this method of treatment has simplified the presentation of a somewhat abstract subject, so that it may be more readily grasped by the average student.

Petrol Engine Construction and Drawing. By W. E. Dommett. 55 pages, 11 by 8½ inches. 26 illustrations. Published by Longmans, Green & Co., Fourth Ave. and 30th St., New York. Price 75 cents, net.

Existing books on machine design have failed to present information to meet the requirements of draftsmen engaged in work dealing with petrol engines and to meet this requirement, a series of drawings was prepared for use at Guildford and Kingston-on-Thames Technical Institutes. These drawings have been embodied in the present book with the view of compiling a text to meet the requirements of technical students, engineers, apprentices and junior draftsmen, who are either engaged on work in connection with petrol (gasoline) engines or are otherwise interested in the subject. Some of the dimensions in these drawings are given in millimeters on account of the extensive use of this system on the continent of Europe. For purposes of reference, a very brief description has been given of the four-cycle and two-cycle engines. The purpose of so doing has been to encourage the student-draftsman to enter into the mechanical principles underlying the operation of the parts which he is drawing in addition to simply producing a view of them for the use of the engineering department. In view of the wide application of petrol engines on motor cars, marine vessels, aeroplanes and stationary engines, it is believed that this work should be one of considerable value.

The Modern Gasoline Automobile. By Victor W. Page. 693 pages, 8⅝ by 6 inches. 380 illustrations. Published by Norman W. Henley & Son, New York. Price $2.50.

In preparing this book, the author's object has been to develop a text on the modern gasoline automobile which will be readily understood by non-technical readers. The usefulness of such a book will be readily appreciated when it is remembered that a large number of the owners of automobiles are business and professional men who have very little mechanical knowledge. The present book has been written primarily for the benefit of such readers and with this purpose in view, technical terms have been eliminated from the text as far as possible. At the same time, the author has appreciated the necessity of entering into a considerable amount of detail in order to present the subject in an adequate manner. This is probably one of the most striking differences between this book and preceding books which have been written by other authors with the view of covering the same subject. It is an established fact among automobile builders and sales agencies that many persons are deterred from purchasing an automobile, not on account of lack of means for the initial investment or provision for maintenance, but owing to the somewhat general belief that the upkeep of a car requires considerable mechanical ability. While this is undeniably true, any business man should be able to acquire much of the necessary knowledge concerning the operation and maintenance of a car from Mr. Page's book.

Hygiene for the Worker. By Dr. William H. Tolman. 231 pages, 7⅜ by 5¼ inches. Profusely illustrated. Published by the American Book Co., New York. Price 59 cents, postpaid.

It has been truly said that good health is the first requisite of success in any business undertaking. This is particularly true in the case of industrial workers who are more or less dependent upon physical strength in earning their livelihood. Dr. Tolman has had unusual opportunities for studying the conditions governing the health and general welfare of industrial workers and has developed his text with the particular object of making it acceptable reading for workers who are just starting upon their business career. The fault of many books intended to teach methods of hygiene is that they have been made more or less dependent upon a knowledge of anatomy. In the present book, such scientific terms have been entirely eliminated and a simple description is given of the necessary steps for the young worker to take in order to preserve his health and vitality in the best possible working condition. The book is freely illustrated with drawings especially prepared for the purpose and should be of particular interest and value to the class of readers for which it is intended. The chapter titles are as follows: Applying for a Position; Preparing for the Day's Work; Good Habits for the Workmen; Suitable Clothing; Food and Drink; Alcohol and Tobacco; The Noon Hour; Hygiene of the Workroom; Fatigue; After Hours; Holidays and Outings; Choice of Occupation; Occupational Dangers—Accidents; Occupational Dangers—Poisons and Fumes; Fire; First Aid to the Injured; Tuberculosis, etc.

Commercial Engineering. By "A General Manager" (Alfred B. Liversedge). 369 pages, 8¾ by 6⅛ inches. Published by Emmott & Co., Ltd., 65 King St., Manchester, England. Price $1.80.

The text presented in this book reproduces a series of articles which recently appeared in the *Mechanical World*. The primary aim of the text was to fill in the gap which exists between the information acquired from any form of technical or business education and the actual application of the knowledge so acquired in commercial or engineering fields of endeavor. Business aptitude or the ability to handle engineering work to advantage can only be acquired through years of actual experience, and such experience necessarily entails making a start in positions of minor importance. One of the objects of the matter presented in this text is to afford a means for employes holding positions of minor importance to get in touch with the work carried on by the directing officials of large corporations. It is believed that a study of such methods will prove of particular value, as a knowledge of the workings of the organization of large corporations will place the employe in a position to undertake readily the duties of a more important position, when the opportunity of so doing presents itself. In addition, this book presents information which should be of value to the man higher up in pointing out the possibilities of markets which exist for engineering products, and the best methods of conserving these markets for his company. One of the valuable features of the method of presentation of this text is that it will appeal to a wide circle of technical readers occupying positions of varying importance.

NEW CATALOGUES AND CIRCULARS

Edwin Burhorn Co., 71 Wall St., New York. Catalogue of Burhorn and "Acme" cooling towers.

American Engineering Co., Philadelphia, Pa. Report of tests made on Taylor gravity underfeed stokers.

New Jersey Foundry & Machine Co., 90 West St., New York. Circular of cranes, tracks, trolleys and hoists.

Green Fuel Economizer Co., Matteawan, N. Y. Booklet entitled "Best Proportions of Boiler and Economizer Surface."

George Nash Co., 217 Pearl St., New York. Card illustrating "Perfection" spring winder for winding springs by hand or in the lathe.

Otto Gas Engine Works, 33d and Walnut Sts., Philadelphia, Pa. Special number of the *Otto Cycle* describing the Otto horizontal crude oil engine operating on the Diesel principle.

W. S. Rockwell Co., 50 Church St., New York. Catalogue 16 on semi-automatic furnaces for annealing, hardening, tempering, and heat treating, aluminum, brass, copper, german silver, sterling silver, steel, etc.

Kern Machine Tool Co., Hamilton, Ohio. Circular of sixteen-inch ball bearing, sensitive type, drilling machines furnished in 1-, 2-, 3- and 4-spindle combinations, with and without table elevating screw.

Emmert Mfg. Co., Waynesboro, Pa. Catalogue No. 12 of Emmert vises, comprising patternmakers' and woodworkers' universal vises, toolmakers' and machinists' universal vises, machinists' plain vises and combination pipe vises.

De Laval Steam Turbine Co., Trenton, N. J. Booklet on the new De Laval steam turbines with velocity stages, built in sizes up to 600 H. P., and suitable for direct connection to centrifugal pumps, blowers, small generators, etc.

Watson-Stillman Co., 192 Fulton St., New York. Catalogue No. 88 on hydraulic leather belt presses, listing six distinct types of leather presses; also hydraulic pumps, accumulators, fittings, etc., generally required with hydraulic presses.

Otis Elevator Co., 11th Ave. and 26th St., New York. Catalogue of inclined elevators for quick handling of freight and merchandise, truck elevators, overhead carriers, dock elevators, ramp elevators, dumbwaiters, horizontal conveyors, etc.

George W. Richardson, 4212-16 24th Place, Chicago, Ill. Circular of the Richardson direct-reading metal slide-rule, having distinctive features; also Johnson's combination pocket rule made of german silver, forming a hook-rule, caliper-gage, protractor, triangle, or try-square.

Green Fuel Economizer Co., Matteawan, N. Y. Catalogue of standard and special fuel economizers; mechanical draft outfits; heating, ventilating and drying outfits; hot blast heaters; steel plate fans; motor- and engine-driven fans, cast-iron volume blowers, exhausters, etc.

Cincinnati Precision Lathe Co., Cincinnati, O. Catalogue of Cincinnati precision lathes which have the following features: no cone pulleys, continuous spindle bearings, absence of belt pull on spindle, variable speed and reverse without shifting of belts, permanency of alignment, etc.

Cochrane-Bly Co., Rochester, N. Y. Circular on the Cochrane-Bly universal shaper which was illustrated and described in the October number. The shaper is designed especially to meet the needs of tool- and die-makers, being adapted to produce accurate work on dies, special tools, jigs, etc.

Celfor Tool Co., Buchanan, Mich. Table of feeds and speeds for Celfor drills working in cast iron, medium and hard or very tough steel, ranging from ¼ inch to 3 inches diameter. The tables are printed on "Crystaloid," in convenient shape for hanging up in the shop for ready reference.

Hess-Bright Mfg. Co., 17 E. Erie Ave., Philadelphia, Pa. Data sheets on ball bearings comprising propeller shaft ball bearings, mounting for double exhaust fan, two direction thrust bearings, special bearings for automobile steering pivots, vertical shaft bearings, and classified index to titles of ball bearing data sheets.

Crocker-Wheeler Co., Ampere, N. J. Bulletins Nos. 150 and 158, superseding Bulletins Nos. 114, 133 and 123, on coupled and belt type alternating-current motors two- and three-phase 50 KVA and up; and adjustable speed motors 1/3 to 32 H. P., speed ranges 2 to 1, 2.5 to 1 and 3 to 1, made in eleven frame sizes.

Manning, Maxwell & Moore, 85-89 Liberty St., New York. Twelve page bulletin descriptive of Shaw electric monorail system with fixed tongue switch which effects an advance and improvement in monorail construction, eliminating the danger of accidents and delays incident to the use of the moving-tongue type.

Foster Machine Co., Elkart, Ind. Circular of plain head and geared head turret lathes, plain head and geared friction head screw machines, universal or set-over turret lathes, special friction head

CONTENTS FOR DECEMBER

The first column of page numbers applies to the Engineering and Railway Editions: the second to the Shop Edition.

screw machines, cock grinder for grinding water and gas cocks up to two inches diameter, tap holders, box tools and other accessories.

Vulcan Engineering Sales Co., Fisher Bldg., Chicago, Ill. Catalogue of punches, shears, rolls, bulldozers, etc., made by the Rock River Machine Co., comprising the "Badger" single end punch and shear, "Badger" single end punch, "Badger" coping punch, "Badger" power plate bending roll and air compressors for general purposes.

Platt Iron Works Co., Dayton, Ohio. Catalogue of Platt horizontal and vertical centrifugal pumps, illustrating different forms of centrifugal pumps adapted to many kinds of service. Users of this apparatus will find interesting and valuable data on the general subject of centrifugal pumps and the conditions necessary for their economical use.

De Laval Steam Turbine Co., Trenton, N. J. Catalogue and treatise on the De Laval steam turbines, containing 120 pages, 6 by 9 inches. The relative advantages of the several fundamental types of turbines are discussed and much space is devoted to a discussion of the "speed-compromise" problem. The publication is an interesting and valuable contribution to trade literature.

Foote Bros. Gear & Machine Co., 210-220 North Carpenter St., Chicago, Ill. Price list of standard gears, comprising spur, bevel, worm gears, raw hide pinions and reducing gears. The catalogue contains 240 pages and comprises considerable data on gear elements that are required in the design and cutting of gearing; also weight tables, gages, drill sizes, thread shapes, power of belting, capacity of cisterns and tanks, etc.

Niagara Machine & Tool Works, Buffalo, N. Y. Catalogue No. 50 of tools and machines for working sheet metals, tinsmiths' and roofers' tools, etc., comprising folders, brakes, bench machines, beaders, flangers, groovers, double seamers, forming rolls, tube formers, stakes, snips, roofing tools, gutter beaders, notchers, rotary shears, foot squaring shears, lever punches and shears, power squaring shears, power rotary shears, etc.

William Cramp & Sons Ship & Engine Bldg. Co., Philadelphia, Pa. Pamphlet on gear bronzes describing six kinds, including Parsons' manganese bronze. The characteristics of each kind are given with illustrations showing application in use. The bronzes named range from the type suitable for light loads and high speeds to Parsons' manganese bronze adapted for heavy loads and slow speeds, under excessive strain and shock.

National Tube Co., Frick Bldg., Pittsburg, Pa. Bulletin No. 11 on "National" pipe, and defining "spellerizing" which is a method of treating metal. The heated bloom is worked by rolls having regularly shaped projections, and then by smooth face rolls, the result being a uniform dense texture of the steel which is better adapted to resist pitting and corrosion than is the structure of common steel. A list of bulletins published by the company is also included.

National-Acme Mfg. Co., Cleveland, Ohio. Calendar for 1912-13, made in the form of a wall pocket, having two openings through which the calendar for the month and advertisements of the National-Acme automatic screw machine appear. The leaves can be removed and transposed to the back, keeping the entire calendar for the year intact, if desired. The illustrations and print appear in white on a black background, creating a very pleasing effect. A limited supply is available for distribution.

General Electric Co., Schenectady, N. Y. Bulletin A 4037 on isolated and small plant switchboards; A 4036 (superseding bulletin 4917) on direct-current exciter panels; 4974 on current limiting reactances; 4993 (superseding bulletin 4858) on type RI single-phase motors; A 4004 (superseding bulletin 4836) on the G-E steam flow meter; A 4034 on type W long-life flame arc lamps; and A 4039 on direct-current motor-starting and speed-regulating rheostats and panels, superseding bulletins 4600, 4599, 4532 on the same subject.

Pennsylvania R. R. Co., Philadelphia, Pa. Booklet on the American Land & Irrigation Exposition held in New York City November 15 to December 2 at the 71st Regiment Armory. The P. R. R. Co. in common with other progressive railroads, is educating farmers to produce more and better crops. Larger crops mean more freight and merchandise to be transported, more passengers and better dividends. The booklet is illustrated with examples of farm products and is one of a series of interesting and valuable farm publications issued by the company.

Earle Gear & Machine Co., Wyoming and Stenton Aves., Philadelphia, Pa. Pamphlet on herringbone gears describing their characteristics and superiority to spur gearing where smooth, uniform transmission is required. Examples of herringbone gears made by the company are illustrated, ranging up to 365 H. P. capacity, in which example the pitch diameters of the gearing and pinion are 76 and 11 inches, respectively, and the face width 21 inches. The pamphlet also illustrates examples of miter and bevel gears, wormwheel balanced gears, etc.

Deane Steam Pump Co., 115 Broadway, N. Y. Catalogue D 167 on sand riddlers; D 169, on hydraulic air-charging device; D 171, on horizontal duplex piston pumps operated by direct-connected gasoline engines; D 202, on duplex steam pumps piston pattern; D 217, on duplex horizontal double-acting power pumps; D 220, on portable mine pumps, outside packed plunger pattern; D 219, on modern water works for town and city supply; supplement B to D 200, on deep well pumping machinery; D 222, on automatic pumps and receivers; D 224, on horizontal double-acting single-cylinder power pumps.

Canton Foundry & Machine Co., Canton, Ohio. Catalogue of "Universal" conductor pipe and eave-trough machinery, paint rolls, drop presses, melting outfits and dies for ceilings, sidings, cornices, etc. Circular of "Universal" garage equipment comprising turntables, jacks and floor cranes. Circular of "Canton" alligator shears made in five sizes ranging in capacity from 1½ inch square round or equivalent cross-section, soft steel or iron, to 3 inches square or equivalent section. Circular of portable floor crane and hoists for use in machine shops, factories, garages, etc. Circular of turntables for shop and factory railways.

Dodge Mfg. Co., Mishawaka, Ind. Abridged catalogue 106-A-12 on power transmission machinery, comprising price lists of steel shafting; keyseating and shouldering shafting; keyseating iron and iron center wood rim pulleys, rope sheaves, etc.; safety collars; flange couplings; compression couplings; universal joint couplings; shaft hangers and adjustable pillow blocks; adjustable ball-and-socket drop and post hangers; countershafts; step bearings; bearing metals; belt tighteners, friction clutches; cut-off couplings; adjustable mule stands; wood split pulleys; iron center wood rim pulleys; machine molded solid iron pulleys, standard iron split pulleys, etc.

Vulcan Engineering Sales Co., Fisher Bldg., Chicago, Ill. Catalogue No. 3 of Hanna pneumatic standard riveters, screen shakers, revolving dumping riddles, oscillators, mold dryers, etc. The principle of the interesting toggle mechanism of the riveter is clearly shown in outline illustrations and by a view of a model furnished to salesmen. Among the advantages claimed are one blow to a rivet, saving of time and air, heavy predetermined compression, reduced wear and tear, etc. The "anatomy" of the Pedrick and Ayer hydro-pneumatic riveter, also controlled by the company, is shown with list of parts. A list of users of Hanna riveters, 1912, and testimonials from users are issued in separate pamphlets.

New Departure Mfg. Co., Bristol, Conn., manufacturer of "New Departure" ball bearings, has issued a series of data sheets devoted exclusively to the adaptability of these bearings to machine tools and shaft hangers. The data sheets cover the three types of ball bearings of "New Departure" manufacture, each of which has its peculiar qualifications. The sheets are 8½ by 11 inches, printed on one side, and have two holes punched in one edge for a loose-leaf binder. They show the design of specific mountings in a milling machine head, speed cones and driving pulley of a drilling machine, an air compressor base with layshaft and crankshaft, a high-speed grinding spindle and a grinding or polishing head. The construction of the "New Departure" shaft hanger is illustrated and described. This hanger is equipped with a ball bearing developed especially for the service. The sheets and loose-leaf binder will be sent free to any address on request, when written on the letter paper of manufacturing concerns.

TRADE NOTES

Reed Mfg. Co., Erie, Pa., manufacturer of vises, has erected a one-story brick addition 50 by 200 feet.

J. N. Lapointe Co., formerly of Marlboro, Mass., manufacturer of broaching machines and broaches, has moved to its new factory in New London, Conn.

Williams Tool Co., Erie, Pa., manufacturer of pipe tools and threading machines, has just erected a two-story brick addition for office purposes.

Oneida Steel Pulley Co., Oneida, N. Y., manufacturer of steel pulleys, has extended its plant by a one-story cement and steel addition 112 by 310 feet.

Wayo Mfg. Co., 642 Ellicott Square, Buffalo, N. Y., has placed on the market a brush-bar belt dressing, consisting, of a bar of dressing with a leather brush fixed in one end for cleaning the belt before applying the dressing.

Duff Mfg. Co., N. S. Pittsburg, Pa., manufacturer of jacks, has recently placed an order with Tate-Jones & Co. of Pittsburg for a

THE DISCRIMINATING PIANO MANUFACTURER

buys <u>the Felton & Guilleaume Imported Steel Music Wire</u> because he has learned that the wire plays the most important part in the tone of the instrument. He has tried out many wires and he knows the Genuine F & G, in either the Black, Red or Green Label grades, is to be depended upon <u>at all times</u> for uniformity of strength and quality.

F & G Wire is now used, also, by manufacturers of Calculating Machines, Typewriters, Automatic Machines, Carpet Sweepers, Toys, Electrical Work, etc., and by hundreds of other manufacturers who have tried out scores of other makes and found by severe comparative tests that the F & G stands in a class by itself for staunch reliability.

If you have trouble in procuring what you need in High Grade Steel Wire, tell us your requirements and let us submit samples, or

Ask for descriptive circular No. 3076.

HAMMACHER, SCHLEMMER & CO.

HARDWARE TOOLS AND SUPPLIES,

4th Avenue and 13th Street New York, Since 1848

large double chamber heat-treating furnace, similar to the furnace installed some time ago by this company for the White Co. in Cleveland Ohio.

Hess-Bright Mfg. Co., 17 E. Erie Ave., Philadelphia, Pa., announces that the interests in the company owned by Mr. Henry Hess have been purchased by the German D. W. F. Co. (Deutsche Waffen-und Munitions Fabriken). The policy of the company will be directed by Mr. Bright, the new president. A. T. Bruezel is the secretary and C. L. McCalla, treasurer.

Edgemont Machine Co., Dayton, Ohio, manufacturer of friction clutch pulleys and power transmission machinery, is now located in its new factory on National Ave. and Niebert St., Dayton. The new plant is large and modern in every respect and considerable new equipment has been installed which has increased the manufacturing capacity about four times.

Skinner Chuck Co., New Britain, Conn., has purchased the planer chuck business of the Francis Reed Co., Worcester, Mass, and has moved the stock of finished chucks and patterns to the plant at New Britain. The Francis Reed Co. manufactures a line of improved drilling machinery and has manufactured the Jordan planer chucks for upwards of twenty years, but has decided to concentrate on the manufacture of its line of drilling machinery.

Union Mfg. Co., New Britain, Conn., has taken over the manufacture of the hand-operated punch, shear and rod-cutting machine formerly made by P. G. H. Bennett & Co., Boston, Mass. The machine will be made in three sizes, and is intended for general use in machine shops, blacksmith shops, garages, etc., for wire and rod cutting, shearing bars and plates, and punching holes. The company will require no new manufacturing equipment for the production of this machine.

Joseph Dixon Crucible Co., Jersey City, N. J. At the regular monthly meeting of its board of directors held October 21, the following changes were made in the officers and directors, on account of the death of the vice-president, William H. Corbin: George E. Long, former treasurer, was elected vice-president to succeed Mr. Corbin; J. H. Schermerhorn, former assistant secretary and assistant treasurer, was elected a director and treasurer; and Albert Norris was elected assistant secretary and assistant treasurer.

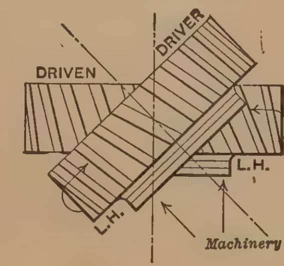
New Process Raw Hide Co., Syracuse, N. Y., has just erected additions which make its plant the largest in the world devoted exclusively to gear making and to gear cutting. The additions are a four-story-and-basement wing, 65 by 180 feet, extending at right angles to the old building, and a heating plant in the rear 50 by 60 feet, housing three 125 H. P. boilers. The new buildings are fire-proof throughout, having steel framework, reinforced concrete walls, brick curtain walls, and steel window sashes. New equipment costing $100,000 has been installed.

Standard Machinery Co., Providence, R. I., has bought six acres in Auburn, R. I., and has made plans for the erection of three buildings. The new location is about four miles from the present plant in Providence, and is on the Shore Line division of the N Y., N. H. & H. R.R. The main building will be 175 feet by 350 feet; and the second building, 100 feet square; and the third building, 60 feet square. The group of buildings will provide about three times the floor area of the old plant. The company expects to occupy the new plant some time next spring.

Palmer-Moore Co., Syracuse, N. Y., for the past two years builders of the Moore two-cycle automobile engine, has increased its capital to $200,000 fully paid in, and will at once begin the manufacture of motor trucks. T. G. Meachem is president of the corporation and T. W. Meachem, vice-president. Charles L. Palmer is secretary-treasurer. The large plant of the Syracuse Stove Works, including three and a half acres of land and 90,000 feet of floor space, has been purchased and will be equipped with new machinery with the view of turning out the first two hundred trucks within six months.

SPIRAL GEARS WITH SHAFTS AT 45 DEGREES ANGLE—I

Shafts at 45 Degrees Angle, Ratio Equal, Center Distance Approximate



The sum of the spiral angles of the two gears equals 45 degrees, and the gears are of the same hand, if each angle is less than 45 degrees. The difference between the spiral angles equals 45 degrees, and the gears are of opposite hand, if either angle is greater than 45 degrees.

Given or assumed:

1. Hand of spiral, depending on rotation and direction in which thrust is to be received.
2. C_a = approximate center distance.
3. P_n = normal pitch (pitch of cutter).
4. α = angle of spiral of driving gear.
5. β = angle of spiral of driven gear.
6. N = number of teeth nearest $\dfrac{2\,C_a\,P_n \cos\alpha \cos\beta}{\cos\alpha + \cos\beta}$

To find:

a. When spiral angles are 22½ degrees.

1. D = pitch diameter $= \dfrac{N}{0.9239\,P_n}$ 2. O = outside diameter $= D + \dfrac{2}{P_n}$
3. T = number of teeth marked on cutter $= N \div 0.788$.
4. L = lead of spiral $= 7.584\,D$.
5. C = center distance $= D$.

b. When spiral angles are other than 22½ degrees.

1. D = pitch diameter of driver $= \dfrac{N}{P_n \cos\alpha}$ 2. d = pitch diameter of driven gear $= \dfrac{N}{P_n \cos\beta}$
3. O = outside diameter of driver $= D + \dfrac{2}{P_n}$.
4. o = outside diameter of driven gear $= d + \dfrac{2}{P_n}$.
5. T = number of teeth marked on cutter for driver $= N \div \cos^3\alpha$.
6. t = number of teeth marked on cutter for driven gear $= N \div \cos^3\beta$.
7. L = lead of spiral for driver $= \pi D \cot\alpha$.
8. l = lead of spiral for driven gear $= \pi d \cot\beta$.
9. C = actual center distance = sum of pitch radii.

Example

Given or assumed:

1. See illustration. 2. $C_a = 4$ inches. 3. $P_n = 10$.
4 and 5. $\alpha = \beta = 22½$ deg. 6. $N = 37$.

To find:

1. $D = \dfrac{N}{0.9239\,P_n} = \dfrac{37}{0.9239 \times 10} = 4.005$ inches.
2. $O = D + \dfrac{2}{P_n} = 4.005 + \dfrac{2}{10} = 4.205$ inches.
3. $T = N \div 0.788 = 37 \div 0.788 = 47$ teeth. (No. 3 cutter).
4. $L = 7.584\,D = 7.584 \times 4.005 = 30.374$ inches.

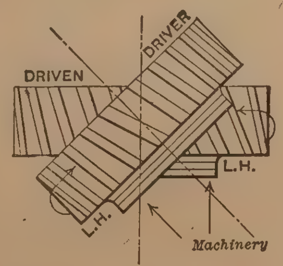
SPIRAL GEARS WITH SHAFTS AT 45 DEGREES ANGLE—II

Shafts at 45 Degrees Angle, Ratio Equal, Center Distance Exact



The sum of the spiral angles of the two gears equals 45 degrees, and the gears are of the same hand, if each angle is less than 45 degrees. The difference between the spiral angles equals 45 degrees, and the gears are of opposite hand, if either angle is greater than 45 degrees.

Given or assumed:

1. Hand of spiral, depending on rotation and direction in which thrust is to be received.
2. P_n = normal pitch (pitch of cutter).
3. C = center distance.
4. α_a = approximate spiral angle of one gear.
5. β_a = approximate spiral angle of the other gear.
6. N = number of teeth nearest $\dfrac{2\,C\,P_n \cos\alpha_a \cos\beta_a}{\cos\alpha_a + \cos\beta_a}$

To find:

1. α and β = exact spiral angles found by trial from $\sec\alpha + \sec\beta = \dfrac{2\,C\,P_n}{N}$.
2. D = pitch diameter of one gear $= \dfrac{N}{P_n \cos\alpha}$.
3. d = pitch diameter of the other gear $= \dfrac{N}{P_n \cos\beta}$.
4. O = outside diameter of one gear $= D + \dfrac{2}{P_n}$.
5. o = outside diameter of other gear $= d + \dfrac{2}{P_n}$.
6. T = number of teeth marked on cutter for one gear $= N \div \cos^3\alpha$.
7. t = number of teeth marked on cutter for other gear $= N \div \cos^3\beta$.
8. L = lead of spiral for one gear $= \pi D \cot\alpha$.
9. l = lead of spiral for other gear $= \pi d \cot\beta$.

Example

Given or assumed:

1. See illustration. 2. $P_n = 8$. 3. $C = 10$ inches. 4. $\alpha_a = 15°$. 5. $\beta_a = 30°$.
6. $N = \dfrac{2\,C\,P_n \cos\alpha_a \cos\beta_a}{\cos\alpha_a + \cos\beta_a} = \dfrac{2 \times 10 \times 8 \times 0.96593 \times 0.86603}{0.96593 + 0.86603} = 73$ teeth.

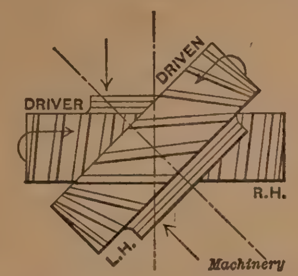
To find:

1. α and β from $\sec\alpha + \sec\beta = \dfrac{2\,C\,P_n}{N} = \dfrac{2 \times 10 \times 8}{73} = 2.1918$; by trial α and β, respectively, $= 14° 44'$ and $30° 16'$.
2. $D = \dfrac{N}{P_n \cos\alpha} = \dfrac{73}{8 \times 0.96712} = 9.435$ inches. 3. $d = \dfrac{N}{P_n \cos\beta} = \dfrac{73}{8 \times 0.86369} = 10.565$ inches.
4. $O = D + \dfrac{2}{P_n} = 9.435 + \dfrac{2}{8} = 9.685$ inches. 5. $o = d + \dfrac{2}{P_n} = 10.565 + \dfrac{2}{8} = 10.815$ inches.
6. $T = N \div \cos^3\alpha = 73 \div 0.904 = 81$ teeth. 7. $t = N \div \cos^3\beta = 73 \div 0.645 = 113$ teeth.
8. $L = \pi D \cot\alpha = \pi \times 9.435 \times 3.803 = 112.72$ inches.
9. $l = \pi d \cot\beta = \pi \times 10.565 \times 1.714 = 56.889$ inches.

Contributed by James H. Carver

SPIRAL GEARS WITH SHAFTS AT 45 DEGREES ANGLE—IV

Shafts at 45 Degrees Angle, Ratio Unequal, Center Distance Exact



The sum of the spiral angles of the two gears equals 45 degrees, and the gears are of the same hand, if each angle is less than 45 degrees. The difference between the spiral angles equals 45 degrees, and the gears are of opposite hand, if either angle is greater than 45 degrees.

Given or assumed:

1. Hand of spiral, depending on rotation and direction in which thrust is to be received.
2. P_n = normal pitch (pitch of cutter).
3. R = ratio of large to small gear = $N \div n$.
4. α_a = approximate spiral angle of large gear.
5. β_a = approximate spiral angle of small gear.
6. C = center distance.
7. n = number of teeth in small gear nearest $\dfrac{2\,C\,P_n \cos\alpha_a \cos\beta_a}{R\cos\beta_a + \cos\alpha_a}$.
8. N = number of teeth in large gear = $R\,n$.

To find:

1. α and β, exact spiral angles, by trial from $R\sec\alpha + \sec\beta = \dfrac{2\,C\,P_n}{n}$.
2. D = pitch diameter of large gear = $\dfrac{N}{P_n\cos\alpha}$. 3. d = pitch diameter of small gear = $\dfrac{n}{P_n\cos\beta}$.
4. O = outside diameter of large gear = $D + \dfrac{2}{P_n}$.
5. o = outside diameter of small gear = $d + \dfrac{2}{P_n}$.
6. T = number of teeth marked on cutter for large gear = $N \div \cos^3\alpha$.
7. t = number of teeth marked on cutter for small gear = $n \div \cos^3\beta$.
8. L = lead of spiral for large gear = $\pi\,D\cot\alpha$.
9. l = lead of spiral for small gear = $\pi\,d\cot\beta$.

Example

Given or assumed:

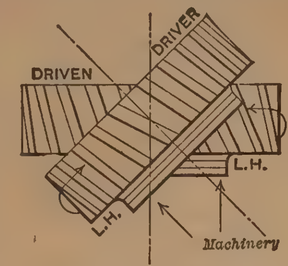
1. See illustration. 2. $P_n = 4$. 3. $R = 4$.
4. $\alpha_a = 50$ degrees. 5. $\beta_a = 5$ degrees. 6. $C = 30$ inches.
7. $n = \dfrac{2\,C\,P_n\cos\alpha_a\cos\beta_a}{R\cos\beta_a + \cos\alpha_a} = \dfrac{2 \times 30 \times 4 \times 0.643 \times 0.996}{(4 \times 0.996) + 0.643} = 33$ teeth.
8. $N = R\,n = 4 \times 33 = 132$ teeth.

To find:

1. α and β from $R\sec\alpha + \sec\beta = \dfrac{2\,C\,P_n}{n} = \dfrac{2 \times 30 \times 4}{33} = 7.273$. By trial $\alpha = 50°\,21'$, and $\beta = 5°\,21'$.
2. $D = \dfrac{N}{P_n\cos\alpha} = \dfrac{132}{4 \times 0.63810} = 51.716$ inches. 3. $d = \dfrac{n}{P_n\cos\beta} = \dfrac{33}{4 \times 0.99564} = 8.286$ inches.
4. $O = D + \dfrac{2}{P_n} = 51.716 + \dfrac{2}{4} = 52.216$ inches. 5. $o = d + \dfrac{2}{P_n} = 8.286 + \dfrac{2}{4} = 8.786$ inches.
6. $T = N \div \cos^3\alpha = 132 \div 0.26 = 508$ teeth. 7. $t = n \div \cos^3\beta = 33 \div 0.987 = 33$ teeth.
8. $L = \pi\,D\cot\alpha = \pi \times 51.716 \times 0.82874 = 134.6$ inches.
9. $l = \pi\,d\cot\beta = \pi \times 8.286 \times 10.678 = 278$ inches.

SPIRAL GEARS WITH SHAFTS AT 45 DEGREES ANGLE—III

Shafts at 45 Degrees Angle, Ratio Unequal, C. D. Approximate



The sum of the spiral angles of the two gears equals 45 degrees, and the gears are of the same hand, if each angle is less than 45 degrees. The difference between the spiral angles equals 45 degrees, and the gears are of opposite hand, if either angle is greater than 45 degrees.

Given or assumed:

1. Hand of spiral, depending on rotation and direction in which thrust is to be received.
2. C_a = center distance.
3. P_n = normal pitch (pitch of cutter).
4. R = ratio of gear to pinion, $N \div n$.
5. α = angle of spiral on gear.
6. β = angle of spiral on pinion.
7. n = number of teeth in pinion nearest $\dfrac{2\,C_a\,P_n\cos\alpha\cos\beta}{R\cos\beta + \cos\alpha}$
8. N = number of teeth in gear = $R\,n$.

To find:

a. When $\alpha = \beta = 22\tfrac{1}{2}$ degrees.

1. D = pitch diameter of gear = $\dfrac{N}{0.9239\,P_n}$. 2. d = pitch diameter of pinion = $\dfrac{n}{0.9239\,P_n}$.
3. O = outside diameter of gear = $D + \dfrac{2}{P_n}$. 4. o = outside diameter of pinion = $d + \dfrac{2}{P_n}$.
5. T = number of teeth marked on cutter for gear = $N \div 0.788$.
6. t = number of teeth marked on cutter for pinion = $n \div 0.788$.
7. L = lead of spiral on gear = $7.584\,D$. 8. l = lead of spiral on pinion = $7.584\,d$.
9. C = actual center distance = $\dfrac{D + d}{2}$.

b. When α and β are any angles.

1. D = pitch diameter of gear = $\dfrac{N}{P_n\cos\alpha}$. 2. d = pitch diameter of pinion = $\dfrac{n}{P_n\cos\beta}$.
3. O = outside diameter of gear = $D + \dfrac{2}{P_n}$. 4. o = outside diameter of pinion = $d + \dfrac{2}{P_n}$.
5. T = number of teeth marked on cutter for gear = $N \div \cos^3\alpha$.
6. t = number of teeth marked on cutter for pinion = $n \div \cos^3\beta$.
7. L = lead of spiral on gear = $\pi\,D\cot\alpha$. 8. l = lead of spiral on pinion = $\pi\,d\cot\beta$.
9. C = actual center distance = $\dfrac{D + d}{2}$.

Example

Given or assumed:

1. See illustration. 2. $C = 12$ inches. 3. $P_n = 6$. 4. $R = 3$. 5. $\alpha = 20$ deg. 6. $\beta = 25$ deg.
7. $n = \dfrac{2\,C\,P_n\cos\alpha\cos\beta}{R\cos\beta + \cos\alpha} = \dfrac{2 \times 12 \times 6 \times 0.93969 \times 0.90631}{(3 \times 0.90631) + 0.93969} = 34$ teeth approximately.
8. $N = Rn = 3 \times 34 = 102$ teeth.

To find:

1. $D = \dfrac{N}{P_n\cos\alpha} = \dfrac{102}{6 \times 0.93969} = 18.091$ inches. 2. $d = \dfrac{n}{P_n\cos\beta} = \dfrac{34}{6 \times 0.90631} = 6.252$ inches.
3. $O = D + \dfrac{2}{P_n} = 18.091 + \dfrac{2}{6} = 18.424$ inches. 4. $o = d + \dfrac{2}{P_n} = 6.252 + \dfrac{2}{6} = 6.585$ inches.
5. $T = N \div \cos^3\alpha = 102 \div 0.83 = 123$ teeth. 6. $t = n \div \cos^3\beta = 34 \div 0.744 = 46$ teeth.
7. $L = \pi\,D\cot\alpha = \pi \times 18.091 \times 2.747 = 156.12$ inches.
8. $l = \pi\,d\cot\beta = \pi \times 6.252 \times 2.145 = 42.13$ inches.
9. $C = \dfrac{D + d}{2} = \dfrac{18.091 + 6.252}{2} = 12.1715$ inches.

New Model "62" Wrench

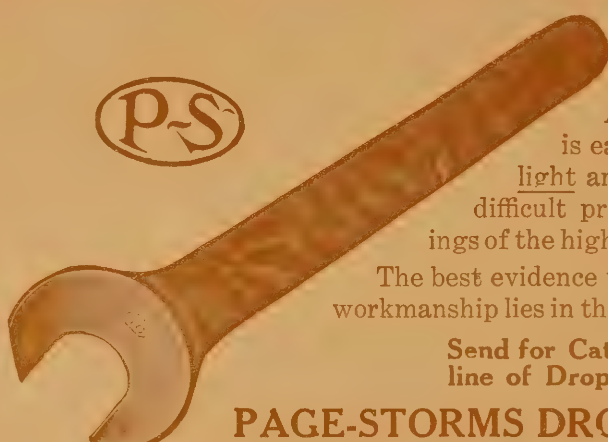
THE VERY FIRST DAY'S USE

of a B & C New Model Screw Wrench proves its worth. You're impressed with its quick and easy adjustment—time saved right at the start. You rely upon its strength and rigidity—that Handle Frame and Bolster all in **one piece** and powerfully braced, inspires confidence. After conquering a stubborn nut that another wrench wouldn't even budge, you appreciate the material in the Reinforced Slide, and in the future you're not afraid to "pull" when occasion demands, because that Unbreakable Bar, forged from **special open hearth steel** stands the strain. Naturally when you need a good Adjustable "S" Wrench—you look for the same trade mark. *Catalogue for the asking.*

Adjustable "S" Wrench

TRADE B&C MARK

BEMIS & CALL HARDWARE AND TOOL CO.
SPRINGFIELD, MASS.



P-S

All the Strength Without the Weight!

Any manufacturer can produce a light wrench. It is easy enough to cut away steel. But to make a wrench light and yet retain the strength of the discarded metal is a difficult proposition. Such wrench making demands drop forgings of the highest grade, plus long experience and specialized methods.

The best evidence that Page-Storms Wrenches embody such material and workmanship lies in the fact, that only from gross misuse are they ever broken.

Send for Catalogue "M" and get acquainted with our line of Drop Forged Wrenches and Special Forgings.

PAGE-STORMS DROP FORGE CO., Chicopee, Mass., U. S. A.

VANADIUM

Blooming Mill Pinions Roll 78% More Tonnage Than Nickel Steel Pinions

A 45 in. Vanadium steel blooming mill pinion, in the LaBelle Iron Works, Steubenville, O., rolled 265,230 tons before replacement. The highest previous record of any 3½% nickel steel pinions in the same mill was 149,035 tons.

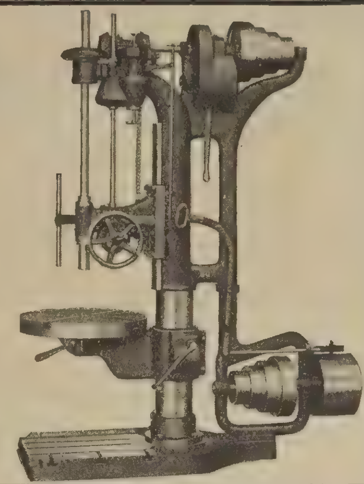
In the same Plant, another set of Vanadium steel pinions have rolled 156,108 tons and are still in good condition.

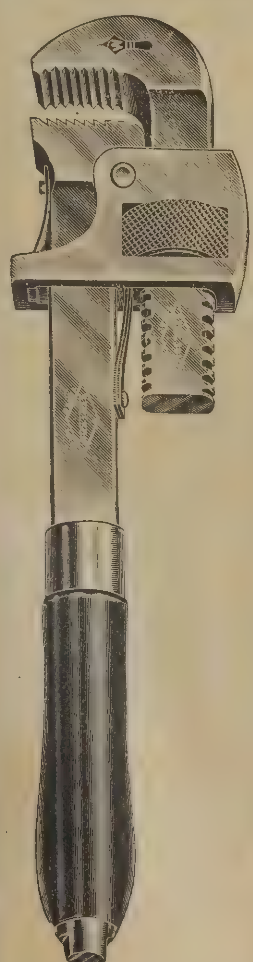
These results are shown by the steel company's records.

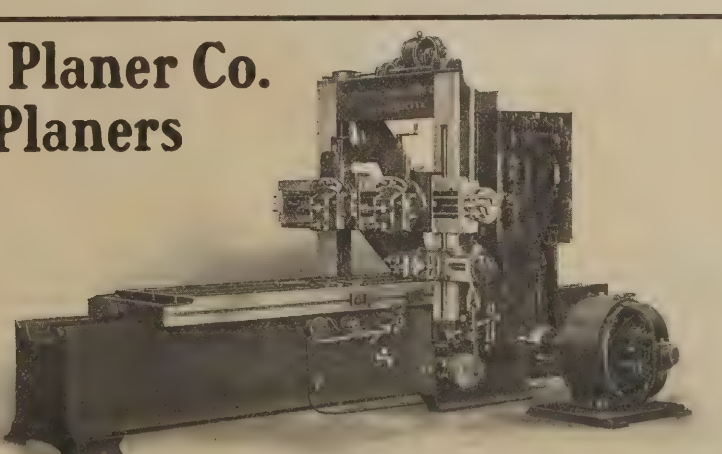
A full account of this and another similar case in another steel mill is published in November "Facts". Write for copy.

Our Ferro-Vanadium is the Standard for Making Vanadium Steel.

AMERICAN VANADIUM COMPANY
325 Vanadium Building PITTSBURGH

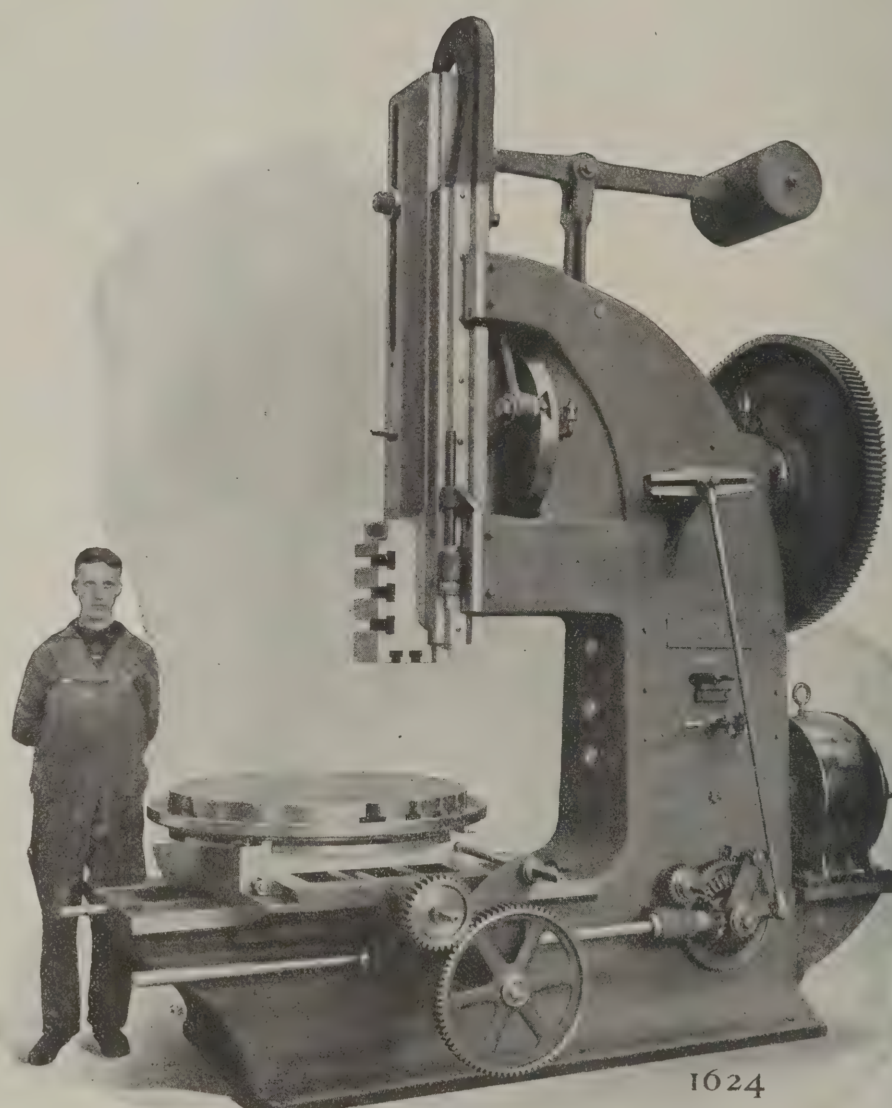






EQUAL TO THE SEVEREST DEMANDS

The Bement Crank Slotter



Will stand up under the heaviest cuts on the toughest metal.

The frame is extremely rigid. It is a continuous box section casting.

The cutter bar is supported close to the work by a rigid knee. The guides are adjustable so that they support the cutter bar to a point immediately above the work being machined.

Table has variable power feeds in all directions.

It also has hand adjustment by convenient means.

All surfaces are scraped to a close bearing.

Powerful drive is provided, either through wide belt and cone of large diameter or by means of direct connected motor.

Sizes—6 to 36 inches.

Write for illustrated circulars and any information desired.

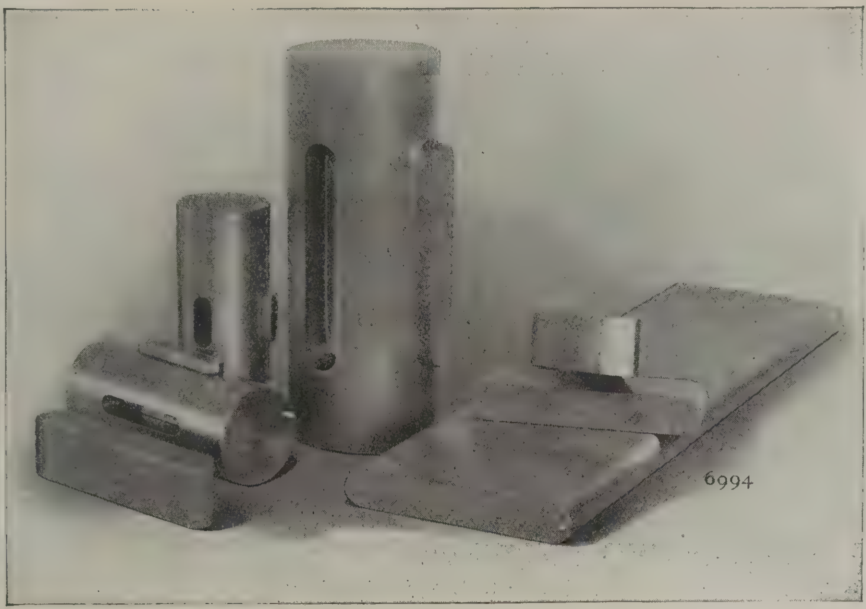
RECTANGULAR KEYS ARE NOW A COMMERCIAL SUCCESS



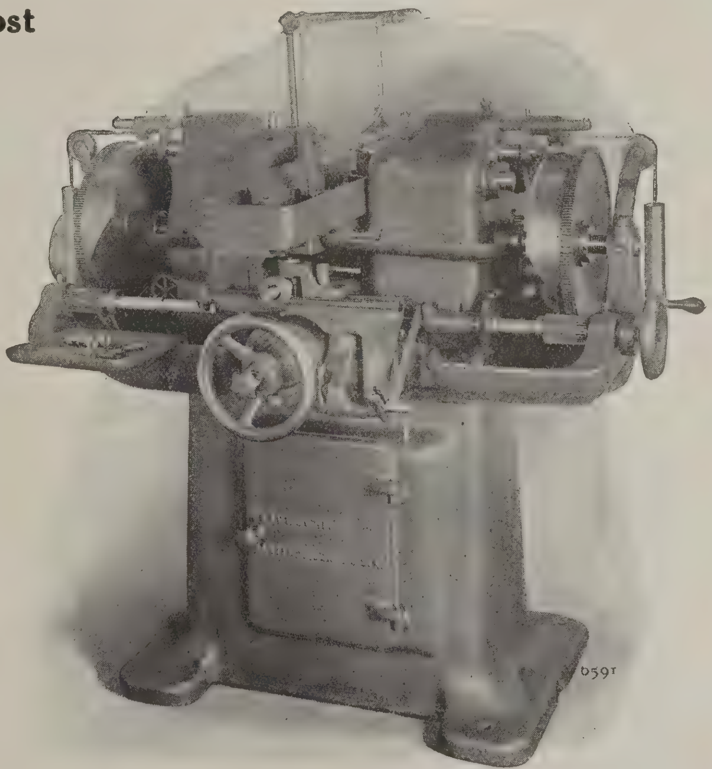
The heretofore excessive cost of milling the keyways has been eliminated by the development of the

P. & W. Spline Milling Machine

which rapidly mills the keyways in one simple operation, with the result that this system of keying is as cheap as any other.

Rectangular Keys by far the most Efficient and Economical

1. They do not materially weaken the shaft. **2.** They will not work loose. **3.** Their shearing strength is practically equal to a solid member. **4.** Two keys may be placed opposite each other on the shaft.



Cost of Cutting Keyways Greatly Reduced

For keyways and slots the Spline Milling Machine has proven the greatest labor-saving machine that has ever been produced. The metal is removed very rapidly and an accurate keyway or slot is cut in a remarkably short time. Automatic features enable one operator to take care of from six to eight machines in some instances.

Accurate Machine Keys Ready to Drive In

without fitting, any width, depth, or taper; finished and guaranteed to micrometer measurements, can be obtained from the **Standard Gauge Steel Company, Beaver Falls, Pa.**

Write for descriptive circular "Spline Milling Machine."

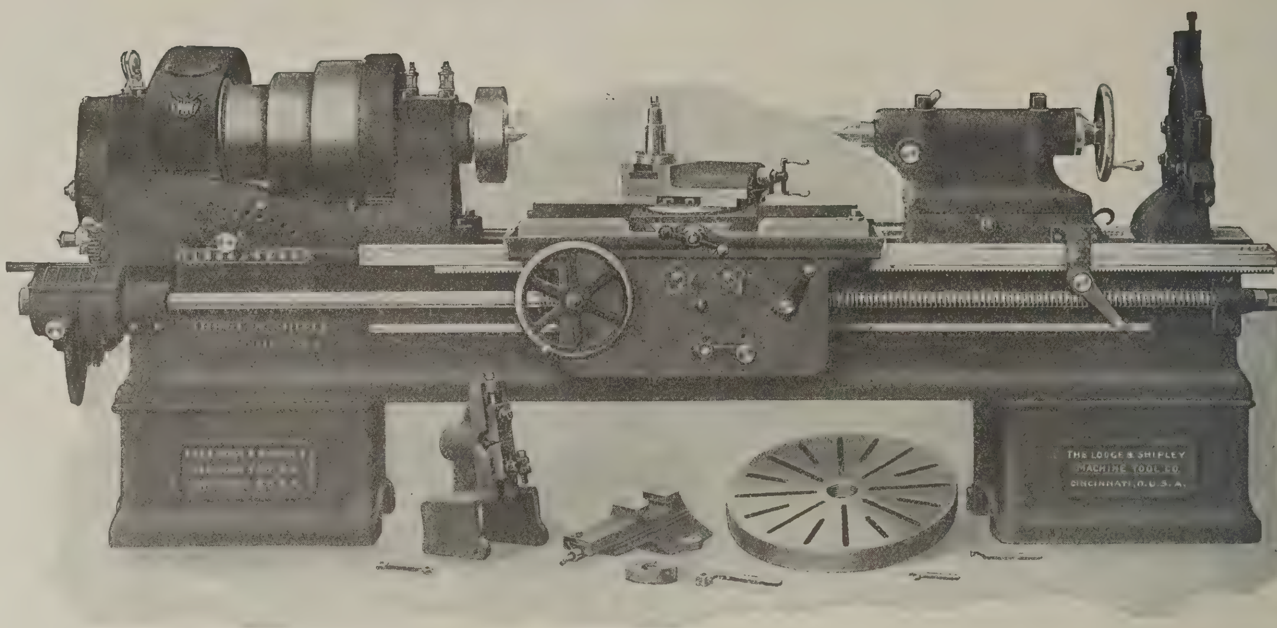
Lodge & Shipley Engine Lathes are



24" Lodge & Shipley Three Step Cone Head Lathe

Drop forged steel quick change gears give 32 changes of feed and thread. Tailstock has tool steel spindle and plug clamp for locking same in absolute alignment. Double plate apron supports all studs front and back.

There continues to be a call for the five or four step cone head engine lathe with the single back gearing. This we can supply.

Many customers are demanding the three step double back geared head with its wider belt and two reductions by gearing—a much more powerful type of head, and generally better adapted to getting the good out of modern tool steels.

Our single pulley drive, with its greatly increased power not only on the two back geared ratios but as well on its open belt of great width, and running over a pulley of extra large diameter, is the type which gives the nearest to ideal conditions for strictly modern lathe work.

Submit your lathe problems to us, preferably with blue prints and full information, and we will give you expert advice gratis.

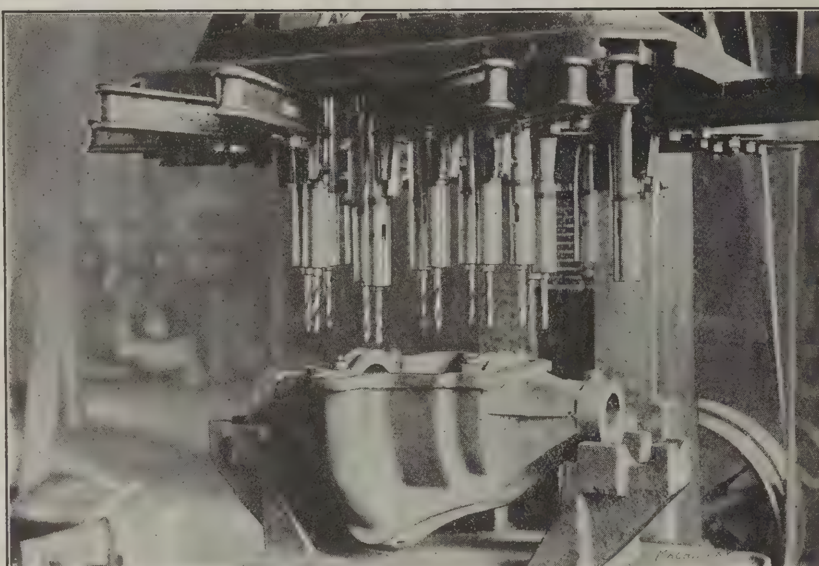
Twelve Holes at a Time



That's the "Baush" way—all drilled together and every hole the same. There's the biggest kind of advantage in this method for any multiple drilling, but in the automobile factory it is absolutely indispensable because there are so many jobs of multiple drilling—bolt holes in hubs, gear cases, rear axle differential housings and the many similar parts that go into an automobile—that one or more Baush Multiple Drilling Machines can be kept busy all the time. A typical example of good automobile practice is the drilling of rear axle differential housings, as shown, at the plant of the Columbia Motor Car Co., Hartford, Conn.

There are twelve $\frac{5}{16}''$ holes, $\frac{3}{4}''$ deep, the work being placed in a cradle, and a jig or template applied through which the drills operate. (To more clearly show the work this template was removed before photographing.) Ten pieces per hour is average production on this work, using a sixteen spindle machine, with four idle spindles, and for over a year and a half the machine has been in constant use on work of this class. A quantity producer, a cost reducer, and with the work once properly set up, accuracy guaranteed.

Are you doing work like this in the old fashioned way—one hole at a time? If so, the "Baush" can probably effect a large saving for you. There's no cost and but little effort required to make sure.

Write us, sending blue prints or sketches of some particular job, or jobs, you have in mind and we'll tell you just what the "Baush" can do on it.

IF YOU HAVE THE WORK— WE HAVE THE LATHE

No matter what your requirements in the lathe line, up to 42-inches swing, there's a **Bradford Lathe** which will fill the bill a little better than *any* other tool and a lot better than *most* of the machines marketed at the same prices. A strong claim; but the "Bradford" can prove it to any lathe buyer who will meet us half way—that is, with a mind open to conviction.

It is workmanship, as well as materials, that tells. In Bradford Lathes they are combined. For instance, small gears are cut from bar steel, and larger gears, where subject to unusual strains, are either steel or bronze; studs are tool steel, hardened and ground; spindles are of high carbon crucible steel, bored from the solid, roughed and finished on the lathe and then ground absolutely true and perfect; the feed rack is steel, made in one section up to 12 feet in length, and in every other detail throughout equally approved practice is followed and modern appliances are used to maintain the high Bradford standard.

Let us send you details on the line—or any single machine— 14 to 42 inch swing.

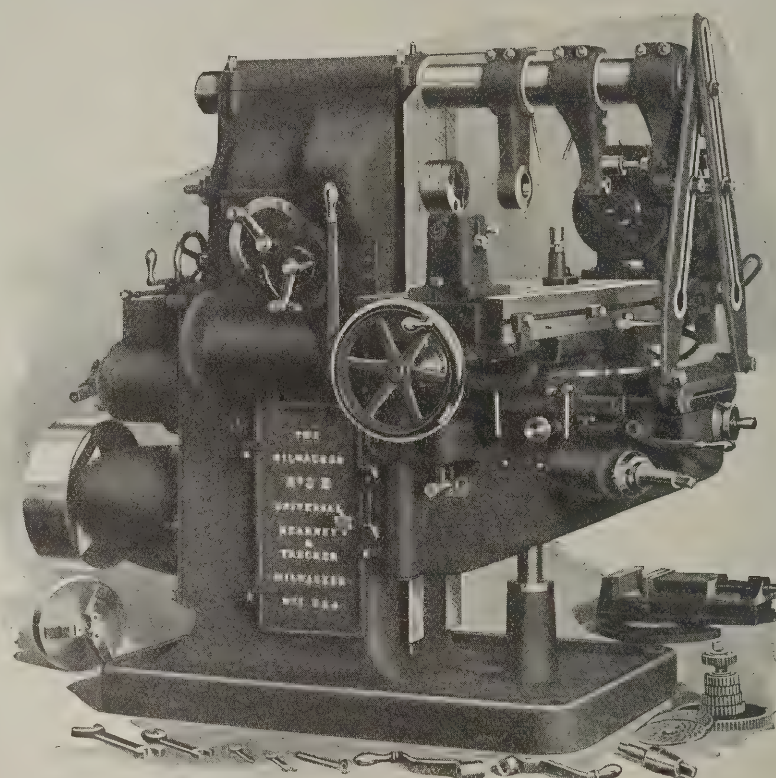
Should the Toolroom Universal be Used For Heavy Manufacturing?

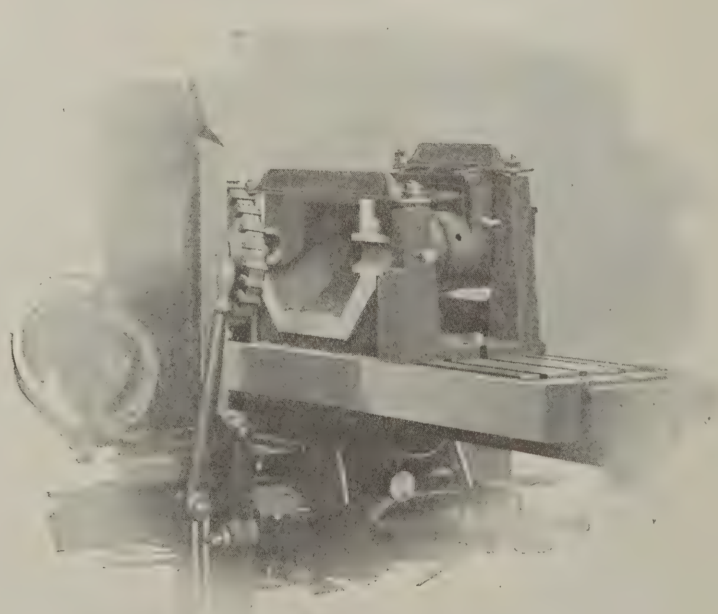


The idea has long prevailed among manufacturers as well as users of Universal Milling Machines that if they could show a high degree of accuracy under test, and be reasonably convenient, nothing more was desired.

Milwaukee Millers

were designed with the firm belief that accuracy was of little value unless there was sufficient stiffness and rigidity to withstand the strain of the heaviest cut and still maintain that accuracy, and that the time spent in perfecting alignment was lost if it disappeared the instant the cutter struck the work.

We can tell but little in this limited space as to how these beliefs are carried into practice, but please notice that the knee is a box section *in fact*, without the usual slotted top (no knee is a box section that has the slotted top) to close when the saddle clamps are set tight or the cut started.



FACE MILLING TRACTION ENGINE CYLINDER

The spindle is of special steel, running in the hardest bronze bearings and these bearings, as well as all gears and bearings of the drive and feed change mechanism, are flooded with streams of oil, insuring the maintenance of their original accuracy through years of service, be it heavy or light.

Should the toolroom Universal be used for heavy manufacturing?

Yes, if it is a MILWAUKEE and shop conditions make it expedient.

Every toolroom and shop foreman should have a copy of our 1912 catalog which shows clearly why the above statement is true.

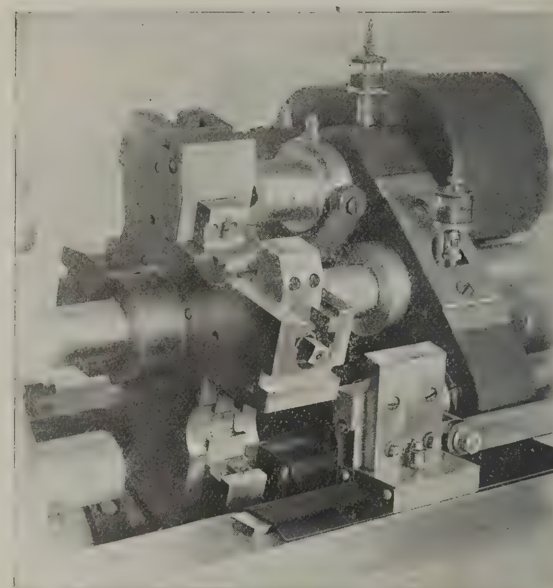
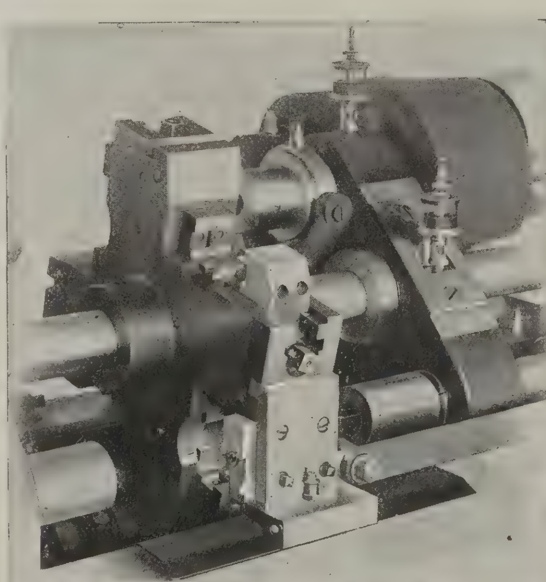
NEW BRITAIN AUTOMATICS

The Steady Rest

The Steady Rest adds greatly to the durability and positive accuracy of the "New Britain" Automatic. Operating upon the sliding key principle, each section of the chuck turret is provided with a slot to receive the tongue of the Steady Rest, which automatically slides into position after each indexing of the turret. This tongue is not the sole support however, the main support being located beneath the chuck turret section—a steel block which slides upon an incline so that adjustments for wear may be taken.



STEADY REST OUT OF POSITION



STEADY REST IN POSITION

Steady Rests are applied to both Single and Double Head machines. They support the turret right at the point where machining is taking place, and no torsional strains affect the accuracy of the machine, as would be the case were the turret supported from the end.

This and other features of these machines, also fine examples of the work they handle, fully described in the New Catalogue.

Ask us to mail a copy and then decide for yourself whether "New Britain" Automatics are applicable to some of your work. They are great labor savers—highly economical—and thoroughly practical on a wide range of product.

64 BIGELOW STREET, NEW BRITAIN, CONN.

AGENTS: Alfred H. Schutte, Paris, Cologne, Brussels, Milan, Bilbao and Berlin. Schuchardt & Schutte, London and St. Petersburg.

JUST OUT

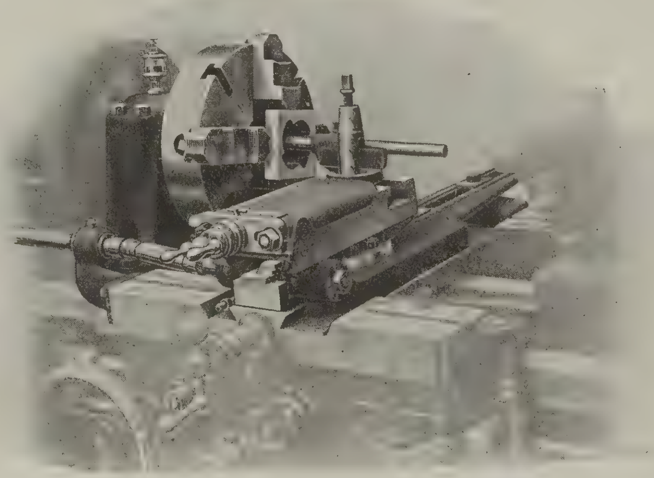

Illustration No. 3 Showing Internal Relief

This lathe has just been put on the market, consequently is the **very latest** in tool room lathes.

The new Relieving Attachment designed for application to this machine is the **only mechanism** of its kind that will perform **all classes** of relieving **without changes** in or **additions** to the regular equipment.

This attachment can be applied to any type of "American" High Duty Lathe, either belt or motor driven, regardless of style of head.

The construction of this mechanism is such as to permit the tool slide to operate at every 30 degrees, thus providing 12 operating positions within a circle.

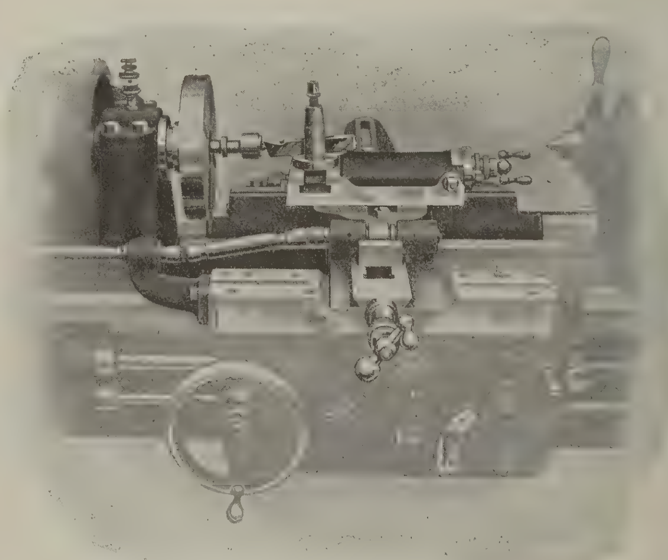

Illustration No. 4 Showing End Relief

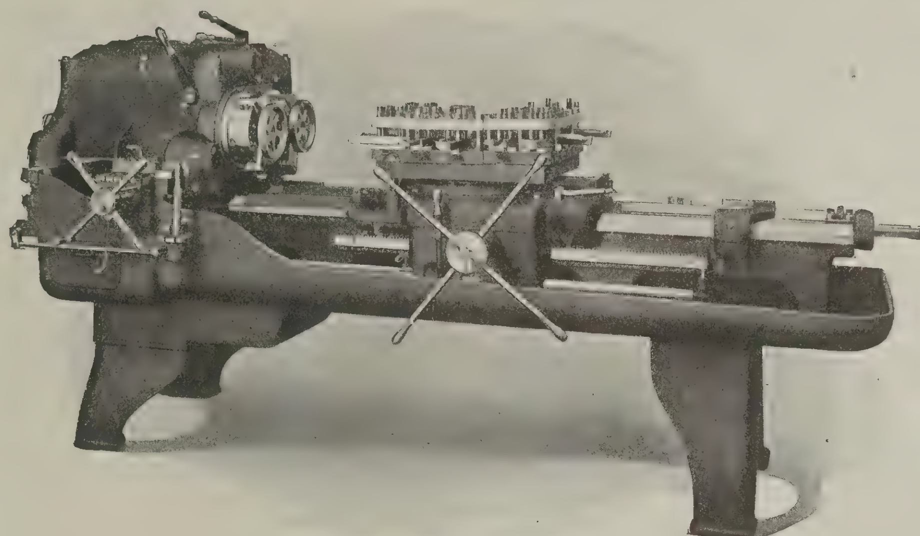
LATHES
PLANERS

THE AMERICAN TOOL WORKS

The Double Spindle Flat Turret Lathe
The Machine for a Continuous Run



THE Double Spindle Flat Turret Lathe meets the demand for largest output. At the expense of a little delay in setting up for a new piece of work—a negligible delay on work which requires no changes in tooling for periods of several days—the Double Spindle will turn out the greatest number of absolutely duplicate pieces at the lowest cost per piece. It is a manufacturing lathe, designed principally to handle chucked work, swings 10 inches on each spindle, and may be used as a Single Spindle Machine if desired, in which case it can carry a chuck 17 inches in diameter.

The Double Spindle Machine gets its output by the use of two sets of tools, carrying on two similar cuts at the same time. Speeds and feeds are the most advantageous, long cuts on both pieces being taken at the same time, and the short cuts, also, taken simultaneously.

The Double Spindle requires a little more time in setting the second set of tools so that they may act in harmony with the first set, but even this is minimized by the auxiliary adjustments provided for many of the tool holders. With the doubling of the tooling there is naturally some restriction of the range of work, but it is nothing compared to the restrictions of other machines offered for manufacturing purposes.

There is a new circular on this machine. Send for it.

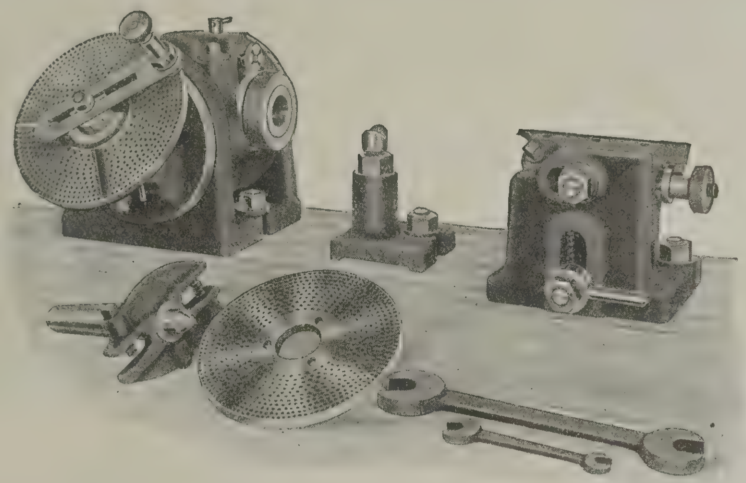
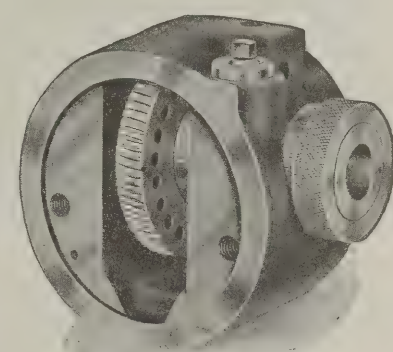
KEMPSMITH

UNIVERSAL DIVIDING HEAD



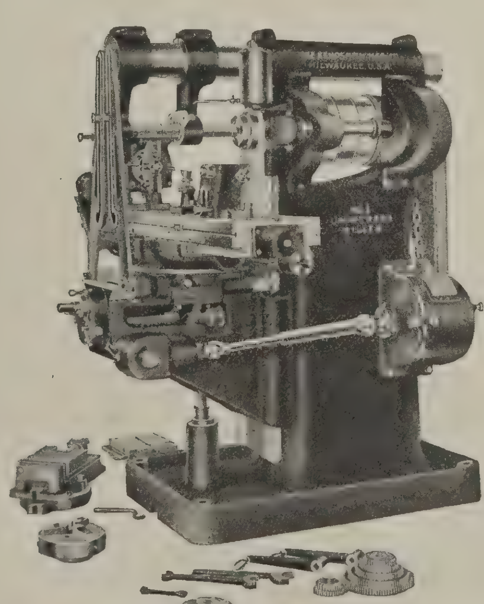
The Most Advanced of All Dividing Heads

Radically Different from any other



The worm-wheel is big ($5\frac{1}{4}''$ dia. on $10\frac{1}{2}''$ head, and $6\frac{1}{2}''$ dia. on $13\frac{1}{4}''$ head) and yet is located centrally within the head proper, between the front and rear spindle bearings.

We arrange the worm at a pronounced angle from the horizontal, and this brings the point of mesh around from under the worm-wheel and gives us practically the whole inside space of the head for the worm-wheel.



And another big advantage results from the same thing, for the index plate, being mounted direct on the worm-shaft, is brought up from the horizontal into a convenient and easily read position, directly in the operator's line of vision, and in much better light.

These are only two of its many good points. All are elaborately described in our Book on the Universal Dividing Head. Get it.

STRONG (see the absence of frail and delicate parts).
SIMPLE and CONVENIENT, nothing complicated.
ACCURATE (every tooth of worm-wheel tested. Average cumulative error .0005.)

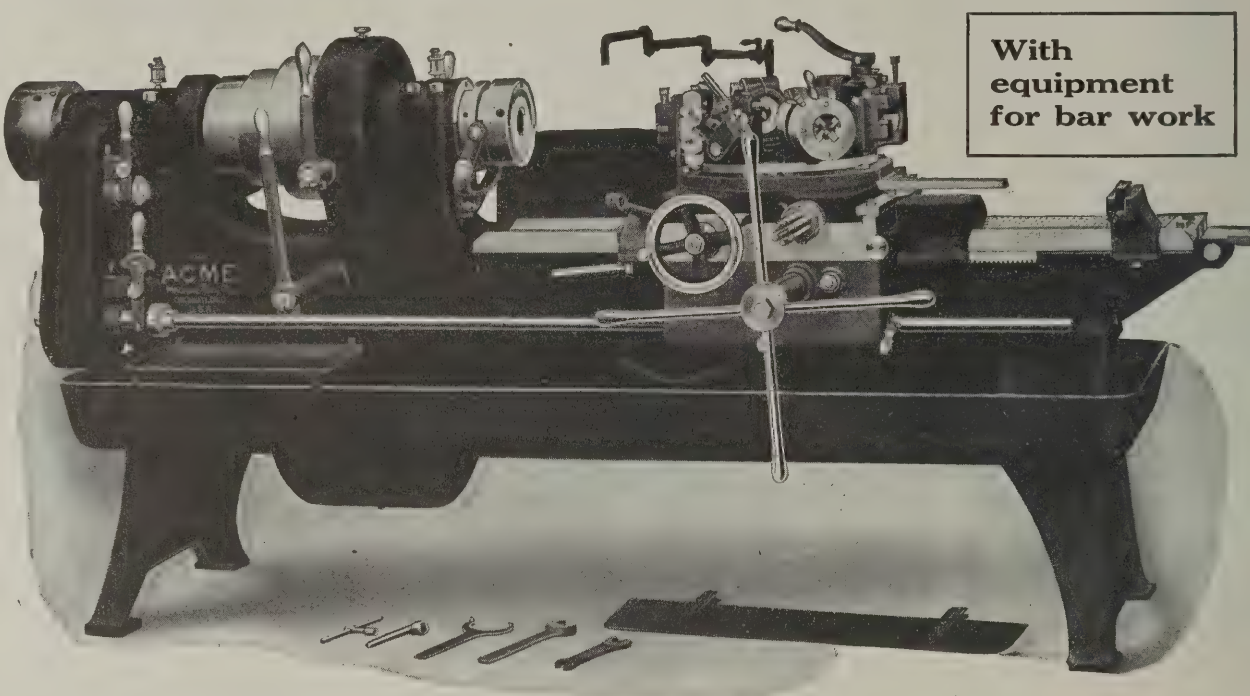
How Would You Handle This Work?

Suppose you were turning a certain fixed quantity of 22 by 1½-inch shafts, with shoulders at both ends, one end threaded and the other drilled and tapped; not enough to keep a turret lathe busy, yet too much to handle profitably on an engine lathe. Suppose, also, you faced practically the same conditions on a quantity of chucked work, say pieces 12 inches in diameter, with three or four operations to complete. What would you do?

With equipment for bar work



The logical, practical, economical thing would be to install an **Acme Combination Flat Turret Lathe**—the machine which **handles both classes of work**, rapidly, accurately and economically with simple tool equipment; the machine with the **perfect** chuck, opened and closed while the machine is running; has no end motion, making it possible to do second operation work requiring **exact** shoulder lengths, and jaws which do **not** overhang, allowing short work to be gripped without tilting the jaws; the machine with the positive, automatic roller-feed which **takes any section of bar**, round, square or hex, **equally well.**

We'd like to send you the catalog showing the flat turret and its rigid tool supporting system, the adjustable stops for each tool and many other advantages in design, construction and operation.

Just Another Proof of "Cincinnati" Efficiency

A little job like machining twenty gas engine connecting rods at one time, only goes to prove that Cincinnati Planers increase production and give maximum planer efficiency. The accompanying illustration shows a 42-inch Two Head Cincinnati Planer of the widened type; the twenty connecting rods are clamped to the platen and the two heads are working on the bosses at either end of the rods. When the bosses are finished on one side they are reversed and finished on the other side. One of these bearings is 4″ and the other 5½″; the rods are steel castings, and the cutting tools are operated at a speed of forty feet per minute with a ⅛″ depth of cut and a transverse feed of 3-32″ per stroke.

Only a planer of the Cincinnati type can handle work in the quantities shown above—and maintain close accuracy in every piece. The quick reverse aluminum pulleys, extra capacity tables, variable speed drive, rigidly braced bed, wide V tracks and other features put Cincinnati Planers in a class by themselves. Send for catalog and details of

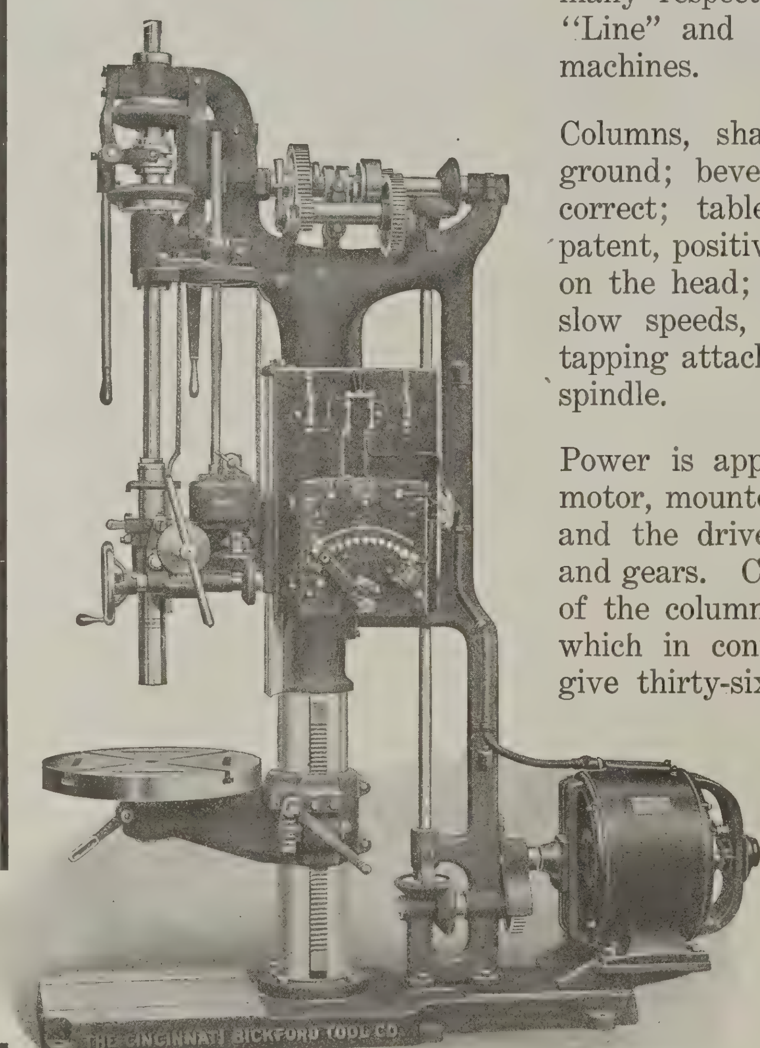
THE CINCINNATI

In This Upright Drilling Machine We Offer

A High Speed, High Power, Essentially Accurate Machine, in Sizes from 24-inch to 42-inch Swing

A machine that fills the demand for a High Speed Drill in which the demonstrated advantages of Cincinnati construction are incorporated, but differing in many respects from the regular Cincinnati "Line" and the entire field of competing machines.



Columns, shafts, sleeves and spindles are ground; bevel gears are planed theoretically correct; tables and arms are very heavy; patent, positive geared feed is located directly on the head; friction back gears give fast or slow speeds, instantly; and patent geared tapping attachment is located directly on the spindle.

Power is applied through a variable speed motor, mounted on the base of the machine, and the drive is by means of vertical shaft and gears. Controller is mounted on the side of the column and provides eighteen speeds, which in connection with the back gears, give thirty-six spindle speeds, all obtainable from the working position. This arrangement gives correct spindle speeds for 70 feet cutting speed on all sizes—and slower speeds are available by the use of friction back gears.

THE CINCINNATI BICKFORD

The Buyer of Our Radial Drilling Machines

Gets Every Operating Convenience that Modern Usage Demands in a Machine of this Class

Not only the superficial convenience, the location of control levers where they are handy, but conveniences that go deeper, that are fundamental to really successful, economical operation. The column, its inner trunk and the arm become practically a single number when the sleeve is tightened; ball thrust and annular bearings are provided; the arm lowers at double its elevating speed; the number of speeds from the variable speed motor drive is practically unlimited, four different combinations of drive can be had; the head is well balanced, stiff, provided with safety stop, dial depth gauge, quick return, ball thrust spindle bearings and many other advantages.

Furnished in two types, the regular for the use of ordinary twist drills, the high power for driving high speed twist drills to limit of endurance.

Dodge Rope Drive in the plant of the Goodyear Tire & Rubber Co., Akron, O.

"Seven Years without a Stop or a Break-down"

THE manager of a well known plant while showing some visitors through the engine room remarked:

"The ropes on these Dodge drives have been doing steady duty for seven years without a stop or a break-down—have never lost a minute in transmitting 1600 H. P."

Listen: The initial cost was $487.20 for the rope, (Dodge "Firmus" Manila) the only wearing part. If the original rope were now a dead loss the net cost per year would be $69.60. To this add interest at 6 per cent, $29.23, a total of only $98.83 for 1600 H. P. per year for rope or a cost per horse-power per year for twenty-three hours daily service of 6 1-6 cents.

These ropes are still doing business and apparently are good for seven years more.

Compare the above with the horse-power per annum cost of any other type of main drive to do this work.

Dodge engineers, with more than a quarter of a century's experience back of them, are ready on call to confer with power users on any changes contemplated in mechanical equipment touching the transmission of power. If you are confronted by a problem put it up to us for solution. **Our business is to make everybody happy, from the chief executive to the chief engineer.**

Your Busy Season?

If work is piling up at some one or two points, put United States Electric "Portables" on the job—it is surprising how they will relieve things. Here's an instance. A manufacturer of small machine parts was running behind his orders; he had speeded-up all along the line, but his drilling equipment was not sufficient to meet the increase. It meant either more equipment, or overtime in this one department. He solved the problem with a single U. S. Portable Electric Drilling Machine. The boy who carried the castings to and from the stationary drilling machines drilled two small holes with the "Portable" before stacking the work for the operator. He saved one operation and released one spindle of the machine—and the congestion at this point was over.

The investment cost was low, the labor cost wasn't increased one cent, the relief was quick and the product was not cheapened or slighted in any way.

Not only in emergencies, but for every day use, U. S. Portable Electric Tools will save—on drilling, grinding, buffing, etc.

Made in many types and sizes, for many classes of work.

Colburn D-3, 24 inch
Heavy Duty Drill Press

A Drill Press With Ball Thrust Bearings

and its work

The performance of the Colburn heavy duty drill press, first brought out in its present model two years ago, was and still is one of the sensations of the machine tool world.

In a test on a D3 24-inch Colburn drill press, a three-inch drill running 188 R.P.M. in cast iron, drilled through a 4-inch block at the rate of 11.25 inches per minute, using a .06 inch feed. In steel, at 100 R.P.M., a 3-inch drill drilled through a 4-inch block in a trifle less than one minute, using a .041 inch feed. The drills were in good condition after each test.

Unless practically all the power applied at the belt had reached the drill, such results as these tests showed would have been impossible. If the machine had been lightly or unskilfully designed, even with no waste of power, the result would still have been impossible.

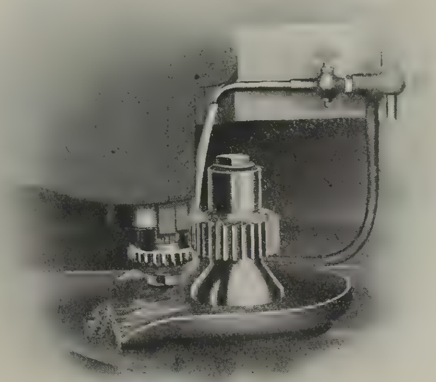
The combination of

HESS-BRIGHT BALL BEARINGS
Built for Endurance

and scientific design produced a drill press that sets a new mark for efficiency and speed.

Our Engineering Department is at the service of manufacturers wishing to improve the bearing performance of their product. Recommendations as to size and mounting will be made, and sketches made without charge from your blue-prints showing how Hess-Brights can be applied.

The Hess-Bright Manufacturing Company
17 East Erie Avenue Philadelphia, Pa.



THE IMPORTANCE OF CUTTER LUBRICATION

FEW mechanics would accept or condemn a machine from the standpoint of cutter lubrication alone; and yet there is no small detail of machine design on which so much depends in the way of accuracy, output and fineness of finish. If the cutting oil or compound is not led properly to the cutting edge, the machine will do less work, and less accurate work; it will show a poorer finish; and the tool will wear out more quickly.

Cutter lubrication is a large matter—not a small one.

Now consider the Gear Shaper. The cutter takes its chip normally on the up- or draw-stroke. The oil falls directly down by gravity onto the advancing cutting edge. That is a simple matter, but no other machine has that simple advantage.

Consider the automatic gear cutter or hobbing machine. The best that can be done with the milling cutter or hob is to wet the teeth before they go into the cut, and wash and cool them off after they come out. Compare this condition with that of the Gear Shaper cutter, which does its actual cutting in a veritable flood of oil.

If the Gear Shaper had no other special advantages in accuracy, output or convenience, it would still be preferred to all other machines on steel work, from the standpoint of cutter lubrication alone.

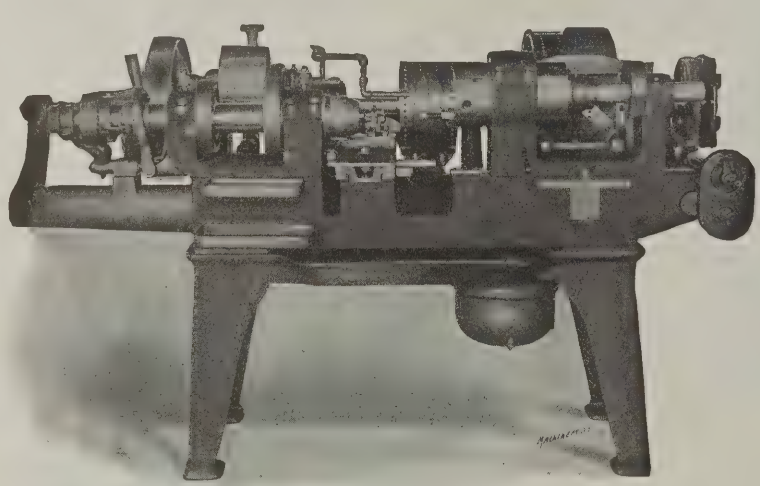
Another Year of Cleveland Automatic Success

1912 has added materially to the number of "Cleveland" installations—thousands of these machines are now in use. We can name more satisfied customers—concerns using from 10 to 200 "Clevelands"—than any other maker of such machines, anywhere. Many of these are early models, 12 to 20 years old, and it speaks well for "Cleveland" design and construction that these machines are turning out work which is satisfactory in every way, though quantities cannot compare, of course, with that of new model machines.

Another point; the cost of maintenance is insignificant. The number of orders we receive for repair parts is less, machine for machine, than for other makes of automatics—and we



make this statement without fear of contradiction. The interchangeability of all parts provides another saving, in case of accident, by which "Cleveland" users benefit.

Other facts of the same nature point the way to highest efficiencies in automatic production. They deserve your most serious consideration. May we send the details?

Piece No. 618. Material, Machine Steel. Made on a 1¼″ Cleveland Automatic Plain Machine. Output, 32 per hour. Send in drawings or samples and we will send you complete specifications, covering outputs, cost of machines, tools, etc.

The *Avey* Ball Bearing Drilling Machine

The Machine that Stands the Speed — Always in the Lead

In certain classes of manufacture where drilling runs almost entirely to the very small sizes, **much higher speeds** should be used than even the ordinary high speeds obtainable on machines adapted to wide range of sizes.

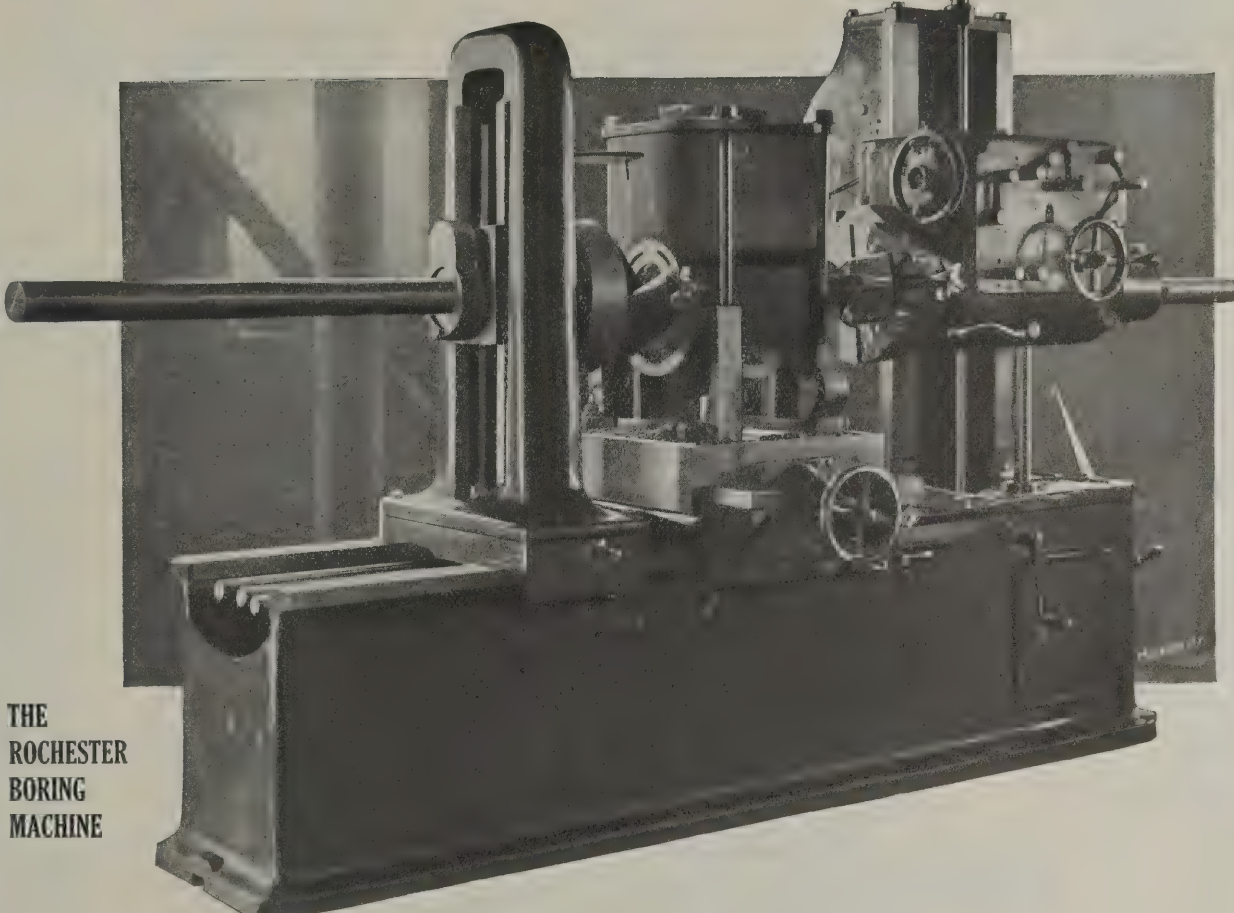
SOMETHING NEW

The Avey Sensitive Drilling Machine No. 1½

Equipped with HESS-BRIGHT bearings throughout, **including** the **Spindle Sleeve** (see cut.) The only sensitive drilling machine on the market with **spindles** running in **Annular** Ball Bearings. Note the clearance of $\frac{1}{32}$" the entire length of spindle sleeve. Note also the Steel Rack inserted in the sleeve. The "Avey No. 1½" is the only machine which can be run at the proper speeds for small drills. **Spindle Speeds of 3000 to 9000 easily obtained,** and can be run at higher speeds if desired.

Write us at once for information.

CINCINNATI PULLEY MACHINERY COMPANY, Cincinnati, Ohio



THE ROCHESTER BORING MACHINE

"The Longer we Run it the More we are Pleased with it"

says this Rochester Boring Machine user. You can see the character of work he is doing; boring large and small gasoline engine cylinders—and gas engine work means straight and accurate boring, always. The letter from the Turner Manufacturing Company speaks for itself, and in a manner peculiar to Rochester users.

Just as this man says, the adaptability of the Rochester is one of its strong points. Why?—Because it has weight, stability, range, every operating convenience, wide spread spindle bearings, continuous traverse of spindle without resetting, and many other details of construction and operation which assure efficiency on various classes of work.

If you do machine work, you do boring, and for your boring you need the "Rochester."

TURNER MANUFACTURING CO.
Established 1872.
PORT WASHINGTON, WIS., U. S. A.
Aug. 17, 1912.

ROCHESTER BORING MACHINE CO., Rochester, N. Y.

Gentlemen:—Replying to your letter of the 15th, we have photographed the machine, working on both the large and small cylinders so as to show its greatest adaptability, which we consider one of the important factors.

As far as the working of the machine is concerned, we can conscientiously say that it is doing all that could be expected of a machine of this kind; in fact, **the longer we run it, the more pleased we are with it, and the more we see its possibilities.**

We have turned out the most perfect 5 H. P. engines with it that we have ever built, and the cylinders were bored with only two cuts, a roughing cut, and reamed with a four blade reamer of our own make. The cylinders were so perfect that the engines tested out in about one-third of the usual time. This is a 5" bore cylinder.

We bored a 12 H. P. cylinder yesterday, 7½" bore, in which there was 1-1000" variation from end to end, and the cylinder was perfectly round so far as we could discover with a micrometer. This was done with a two cutter finishing tool. We expect even better results, both as to output and quality, when we have completed our tool equipment.

You can imagine how well pleased we are with the machine from the foregoing results, especially in view of the unfortunate experience that we have recently gone through with cylinder boring machines. Thanking you for past favors, we are

Very truly yours,
TURNER MANUFACTURING CO.
L. M. Turner, Gen. Mgr.

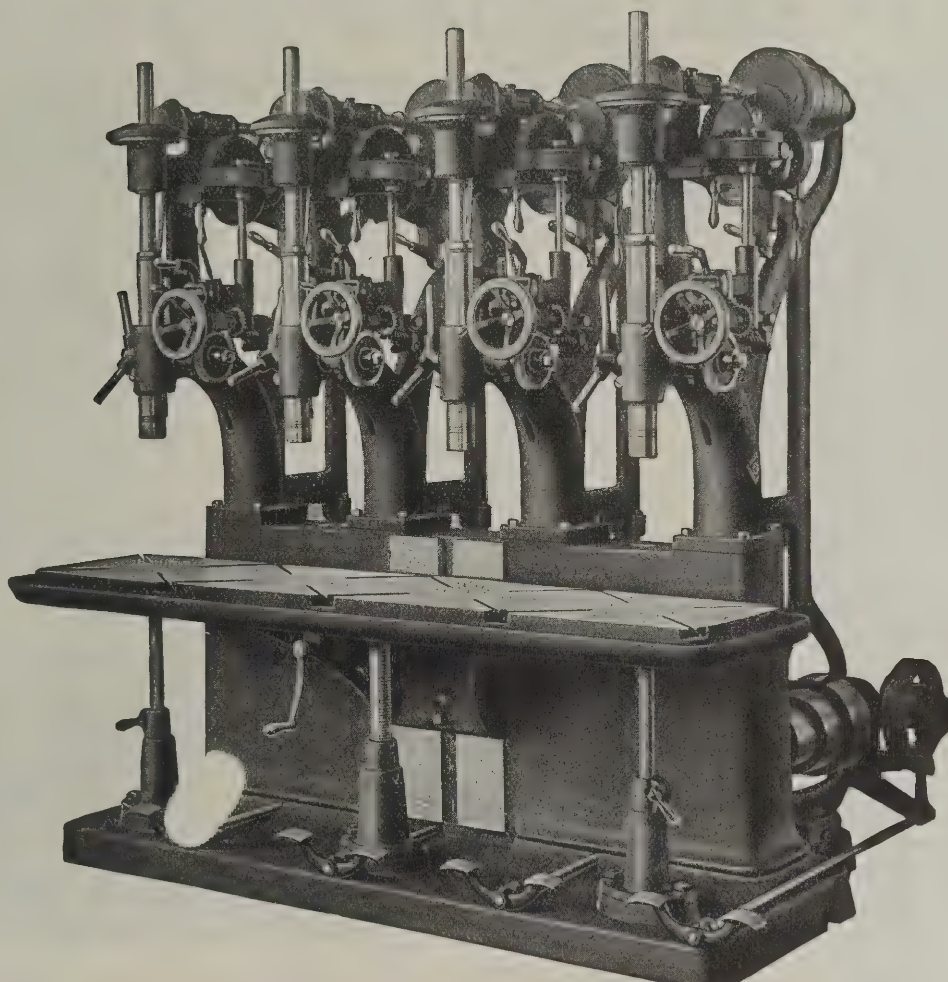
Catalog and full details on request.

ROCHESTER BORING MACHINE CO., Rochester, N.Y.

GANG DRILLS

TRADE W.F. AND J.Co. MARK

We make various sizes, drilling holes up to 2" diameter in solid steel



4 3 or 2 Spindles

22½" Swing Stationary Head Gang Drill (Style B).

LOOK HERE!

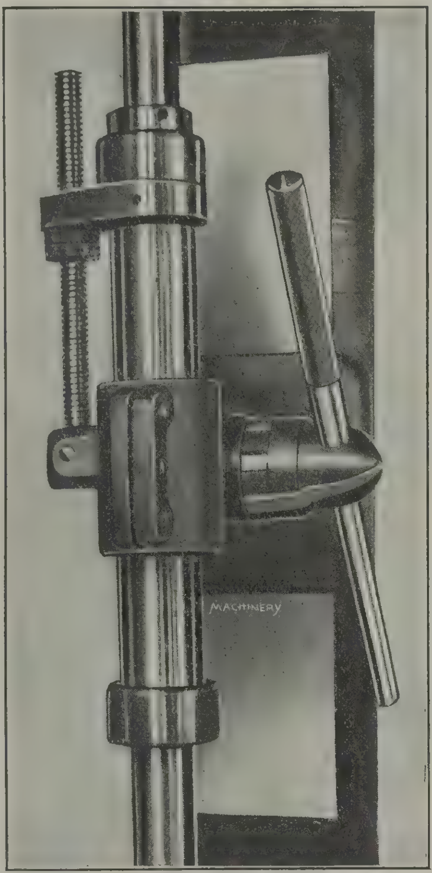
This Gang Drill Has

- Spindle travel of $14\frac{3}{4}$ inches.
- Table travel of $14\frac{1}{2}$ inches.
- Distance from column to spindles $11\frac{1}{2}$ inches.
- Distance between spindles 20 inches.
- A 4-spindle gang weighs 5800 lbs.
- Table measures 17 x 80 inches on 4-spindle gang.

This Gang Drill has driving capacity of a 26-inch swing drill; is equipped with back-gears, self-feed and automatic stop. **Our Geared Tapping Attachment** can be furnished on one or more spindles. Machine is driven by one main driving belt, and yet each spindle can be run separately, or all spindles at one time. We also make other sizes of Gang Drills and complete line of Upright Drills.

231 Ruby Street, Rockford, Ill., U.S.A.

Chas. Churchill & Co., London. F. W. Horne, Yokohama.



Just a Turn of the Wrist

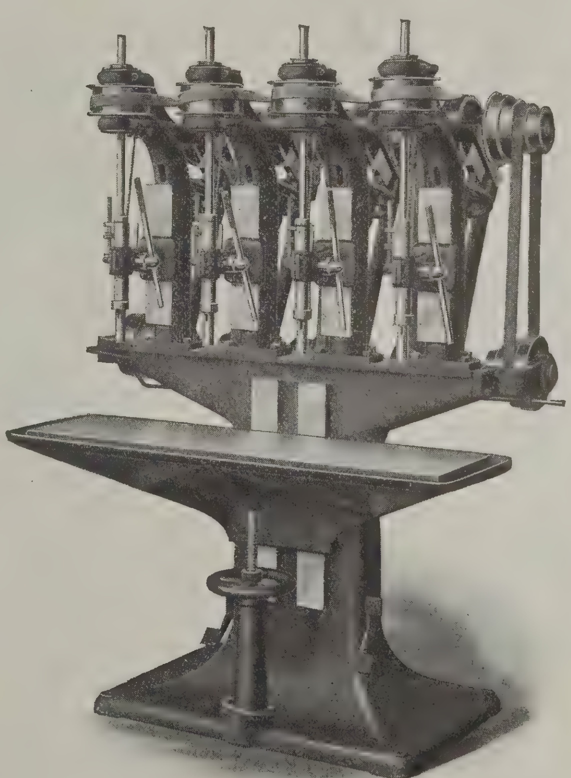
Brings the lever feed to the most convenient operating position—on the **Leland "Sensible Sensitive"** Drilling Machine. This and the positive spindle stop are two of many Leland features which appeal because of their simple effectiveness. The accompanying photographic reproduction of the spindle and head illustrates these points. No more shifting of the head on the column "just a little" to bring the operating lever to a convenient handling position. With the

Leland "Sensible Sensitive"

a simple twist of the wrist upon the knurled section of the lever releases the ratchet pawl so that it may be slipped to the next notch, or brought to any desired position.

The action requires only a few seconds, the pawl springing back into place the instant it is released.

The positive spindle stop is equally efficient. A simple affair, not much of it; but extremely handy when drilling holes to the same depth or counterboring seats for machine screw heads. Just a twirl of the knurled stop collar, followed by the locking collar, completes the adjustment—and no matter where the operator's thoughts are, **he simply can't drill too deep.**



Let us send you Circular R with full details of the

SENSIBLE SENSITIVE DRILL

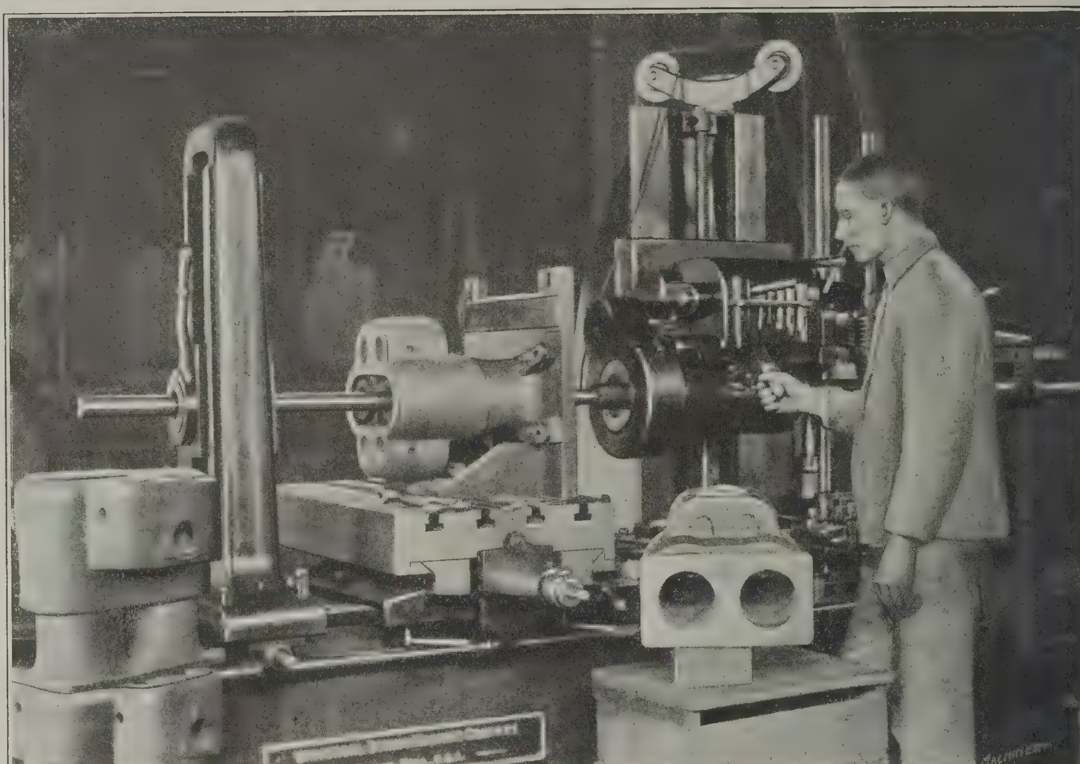
Patents Pending.

BUILT BY

W. H. LELAND & COMPANY

WORCESTER, MASS.

Accuracy is the First Principle of the



THIS principle along with the other "Universal" features goes far to make the machine a power in its field and a prime favorite for modern manufacturing. For instance, in developing, perfecting and building an automobile—a new design, perhaps, which must line up to and pass previous efforts—it is obvious that the highest standards of accuracy must be maintained.

The Brightwood Motor Mfg. Co. of Springfield, Mass.—with just this class of work to handle—have assured themselves that the Universal Boring Machine is the one machine for exact results. They employ the "Universal" for boring gear and crank cases, cylinders, etc., and the machine has proved its efficiency and economy from every standpoint.

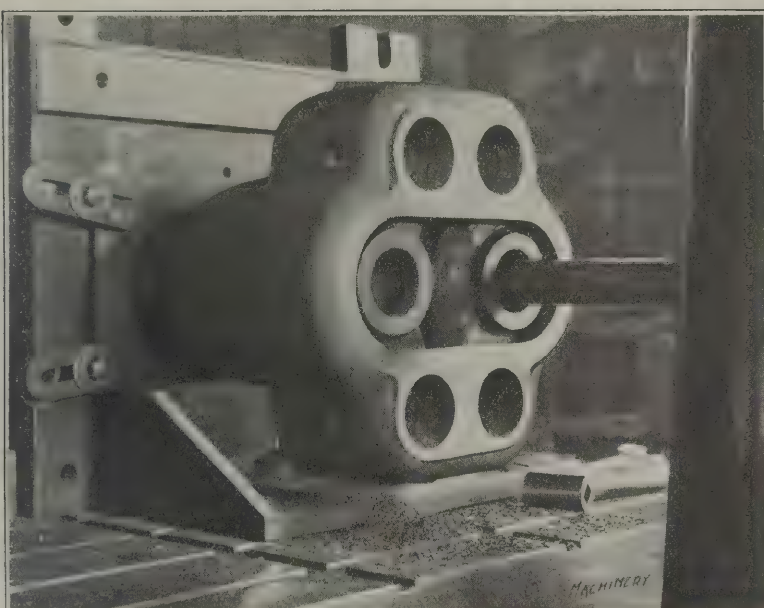
The larger illustration, photo taken at the Brightwood plant, shows the machine boring cylinder castings, one piece in position for working and others piled up in front of the machine. These cylinders, cast "en bloc," are held on the machine in a special fixture, a close view of which is given in the smaller engraving.

UBMCo

UNIVERSAL BORING MACHINE CO.,

AGENTS: Hill, Clarke & Co., Boston, New York, Philadelphia, Buffalo, Cleveland, Chicago.
Brown & Zortman Machinery Co., Pittsburg.
The Mine & Smelter Supply Co., Denver.
Harron, Rickard & McCone, San Francisco, Cal.
Aumen Machinery Co., Baltimore, Md.

Universal (Horizontal) Boring Machine



The cylinders are cast from very close grained Vanadium iron, which is difficult to work, and as they do not depend upon grinding for finishing the piece the boring must be accurate—in fact, the limit set for this work is 0.0005″.

Points which make the Universal Horizontal Boring Machine so successful on automobile work, as on other lines of manufacture, are the ease of operation, the wide range of speeds and feeds obtainable, and above all the dependable accuracy which is a recognized feature of "Universal" boring.

This Universal Boring Machine is adapted for your work.

Write for Special Circulars or list of users in your neighborhood.

Close Limits and Fast Time

are attributes of the **Bullard Vertical Turret Lathe** on automobile work that make it a power in this special line of manufacture. It is not only a pace-maker on production and accuracy, but the machine that stands up on the "long grind"—the machine to assure "results," with the least possible demand on the operator—either mental or physical.

A typical Bullard automobile job is shown in the photograph, taken at the plant of the Pierce Arrow Motor Car Co. at Buffalo—piles of work in the background, the job on the machine.

The 18 inch fly-wheel shown in process is finished all over, as indicated in line drawing, (in two settings) at the rate of thirty-five minutes per piece, averaging sixteen wheels per day for a run extending over several weeks.

Accuracy and high-quality finish are prerequisites in Pierce Arrow work and the results obtained from the first machine warranted the installation of others.

The truck hubs shown in the foreground of the picture constitute another good Bullard job; they are made from steel castings and finished all over; the size limits calling for very accurate work.

The Vertical Turret Lathe

saves time on the single piece or the small lot as well as on the "big run."

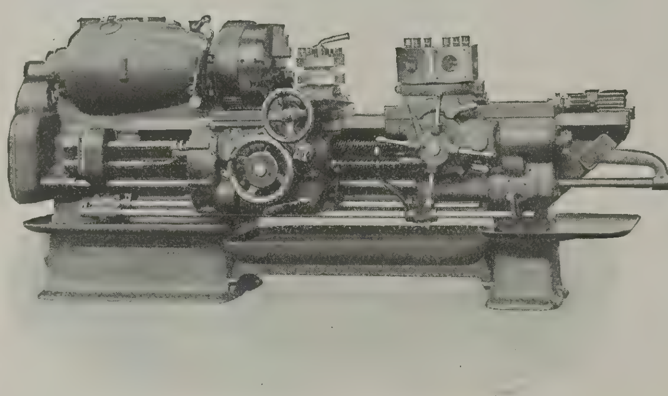
The features which "cut time between cuts" and "cut the cutting time" make proportional savings whether the lot be large or small.

If you are still "without" the Vertical Turret Lathe in your shop, you need our literature —a word will bring it, ask for Catalog MV-22.

THE BULLARD MACHINE TOOL COMPANY

BRIDGEPORT, CONN., U. S. A.

Some of the Libby Turret Lathe Production Records sound like Arabian Nights Tales—But they're Facts!



"Libby" 18" High Power Rapid Production Turret Lathe

"This job has been taking us **6 hours**", confesses an enthusiastic Libby convert. The Libby Lathe now does it in **17½ minutes.** (This is a double steel ball race.)

In another shop—a wide-awake one—a Libby Lathe is replacing two "efficiency" machines, and is saving $250.00 a month! How long before it will pay for itself? **These are facts!** We can prove them. These are only two instances. We have many just like them. There are certain fundamental reasons, discussed in our catalog, why the Libby Lathe can do such things. You owe it to yourself to investigate this remarkable machine.

We make estimates on specifed work. The figures may seem phenomenal, but we back them with a definite and positive guarantee to install a machine and meet them or beat them by actual performance in your own shop.

STOCKBRIDGE TWO-PIECE-CRANK SHAPER

WITH A TEN-CHANGE SPEED BOX GEAR CONNECTED TO MOTOR

Changes of speed can be made instantly. You get just the speed wanted, without engaging intermediate gears. When shaper is stopped, driving shaft is locked; the motor can run without danger of shaper starting up while work is being placed in vise.

Our Two-piece-crank gives results that can be secured with no other shaper.

IT IS A TIME SAVER. **Catalog illustrates and describes the motion.**

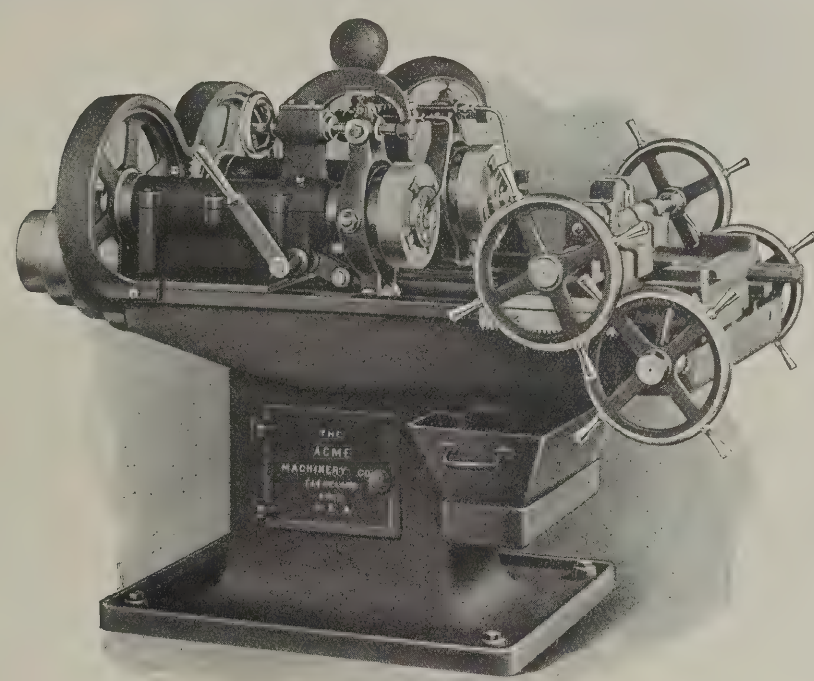
ACME BOLT CUTTERS

Distinct, positive, money-saving advantages are secured by the use of Acme Bolt Cutting Machinery—advantages that can be figured down to their actual dollars and cents values. The simplicity of the Acme Die Head construction is one of these advantages. There are but three principal parts, all made to standard gauges and interchangeable, with a simple adjustment which cannot shake loose and yet is so fine that threads can be cut to absolute sizes.



There are also the advantages of strength and durability—all parts made of tool steel, hardened and ground to size; designed and assembled to withstand the quick action of automatic machinery; every part exposed to view and impossible to clog up with chips or scale. Years of constant use and the few repair parts ever required prove our durability claims.

Acme Die Head simplicity lowers manufacturing costs—enables us to market a die of more than ordinary strength and capacity at a comparatively low price, not alone for the complete die but for separate parts as well, and this saving mounts up to a big total during the useful life of a machine.

Acme Bolt Cutters have advantages of their own—if you cut bolt threads, you will be interested in them—may we send the Catalogue of Acme Bolt and Nut Machinery?

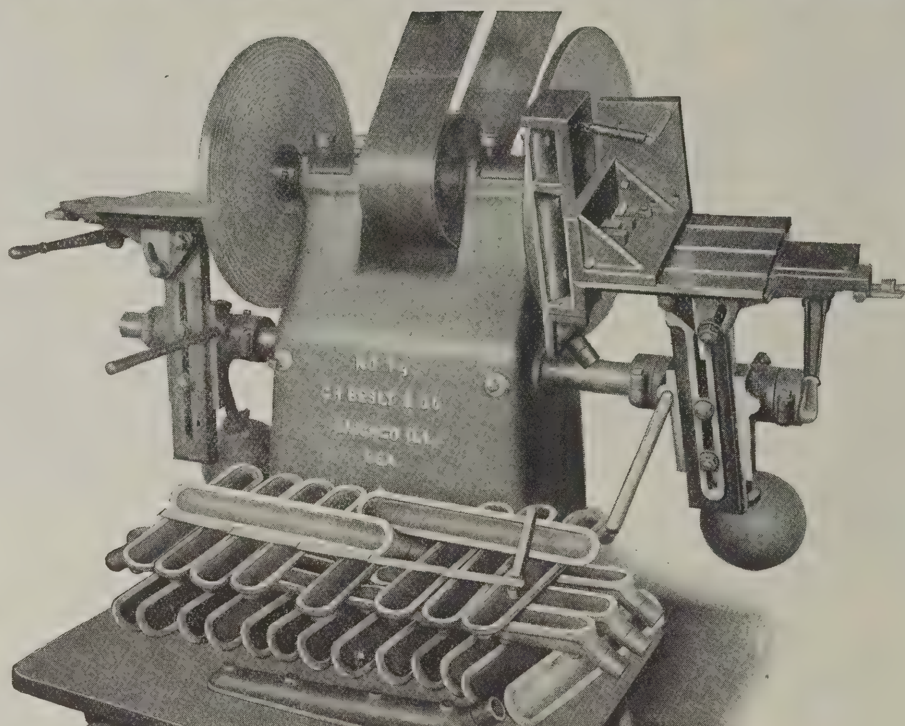
SHIPPING DEPARTMENT

HUNDREDS OF OPERATIONS
On Automobiles and Accessories
FOR BESLY GRINDERS



No. 14—30″=L Besly Grinder with floating workholder on Cast Iron Water Jacket Covers for Automobile Engines

WORKHOLDER

Work is supported *without rigid clamping*, by a V faced holder, hinged on geared lever feed table, so work is free to "float" against grinding disc and clean up flat with the removal of the minimum amount of stock.

Workholder is arranged to be held in two positions on geared lever feed table. In rough grinding, the work is held in a horizontal position to reduce travel of grindings and facilitate removal of scale and excess stock. In finish grinding, work is held in a vertical position, so that all of the ground surface is in contact with the disc wheel while grinding.

ADVANTAGES IN NON-RIGID CHUCKING

To remove stock without rigidly clamping the work is a fundamental principle in Besly Grinding Practice. This is one of the great advantages the Besly Grinder holds over all other types of machine tools on a great many flat surfacing jobs.

Rigid clamping of the work should be avoided if possible, because:

First. More time is consumed in clamping and unclamping.

Second. The work is likely to be presented to the disc wheel in an arbitrary position which requires the removal of more stock than if work is allowed to "float" when forced against the grinding disc.

Third. Thin, fragile work is often distorted by rigid chucking so that, regardless of the accuracy of the surfacing, the work is not flat when released from clamping.

INVESTIGATE

Write today for free copy of 1912 edition of "Besly's Modern Disc Grinding Practice," 112 pages, 103 pictures, and study this important subject. This treatise should be in the hands of every machine manufacturer and his assistants, because it shows the way to reduce costs and improve product.

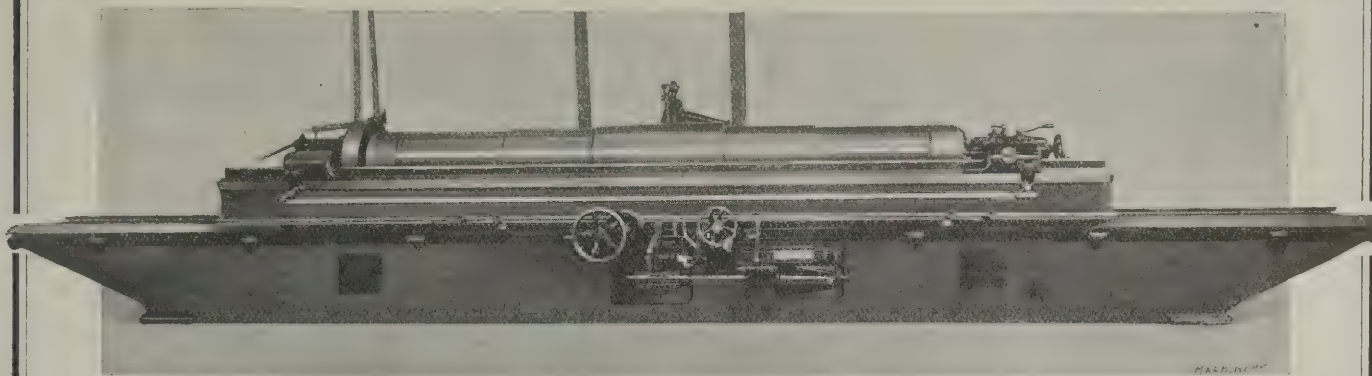
WORKS AT BELOIT, WISCONSIN

BESLY CHICAGO



192 INCHES OF GRINDING EFFICIENCY

are represented in the 20 x 192" Norton Grinding Machine shown above.

This machine, which has been in successful operation at the plant of the National Transit Company at Oil City, Pa., for over four years, is the largest grinding machine we ever shipped, and one of the examples of the adaptability of Norton Machines for heavy work.

The upper illustration shows the machine in operation on a gas engine shaft weighing over 8,000 pounds, which was finished in 8 hours including handling, and in the lower engraving the same machine is featured grinding another special job.

This particular grinding machine has capacity for work up to 20" diameter and 16 feet long, and with this advantage combines all the good points of design and operation that characterize the little 6 x 32" machine. It will handle work up to 12,000 pounds in weight just as readily, easily and efficiently as the small machine grinds the small work for which it is built and adapted.

Norton Quality—strength, rigidity, accuracy—all the grinding essentials—prevail throughout the entire Norton line of Grinding Machines—if you are contemplating the purchase of such a machine why not secure the one that has proved itself. *Catalogue or a representative sent on request.*

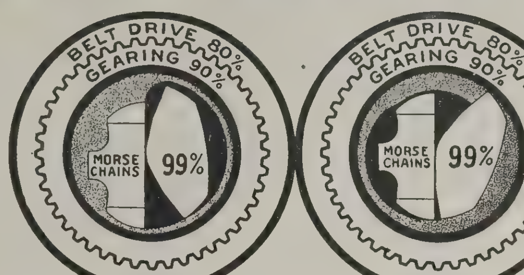
Every Morse Silent Chain Drive is a "Bull's Eye" toward Greater Efficiency and Economy



Efficiency to nearer perfection naturally comes to all machines where the transmission system delivers 99 per cent. of the possible power.

Each machine is then dependable for its full share of work without interruption. Employees can devote their entire time to work in the machine, and as absence of numerous belts makes the lighting conditions better, the work is better done.

Economy is effected:

First—Enormous saving of power (Morse Silent Chains maintain an efficiency of fully 99 per cent).

Second—Less Floor space required. Shortest centers are permissible, and chains average 1-4 to 1-3 the width of belts for the same powers.

Third—Saving of time required to repair broken or parted belts. In a large shop, this saving alone is considerable.

Let us tell you why the exclusive Morse "Rocker-Joint" shown above causes less friction, requires less lubricant, and is more efficient than any other type of joint. You owe it to yourself to know this. Bulletin No. 11 explains in detail.

Morse Chain Company, Ithaca, N. Y.

A-53

TWO TYPICAL DIAMOND CHAIN MOTOR DRIVES

These drives furnish power to automatic screw machines in our own plant. The drive at the right is enclosed in a galvanized iron case, and runs in an oil bath. Motors are each fifteen horsepower. Speed of motors 625 r.p.m. Teeth on motor sprocket 19. Speed of driven shafts 440 r. p. m. Chain speed 990 feet per minute. With all machines running, motors deliver their full horsepower.

These chains have proved eminently satisfactory during four years service. The one which is enclosed is, of course, quieter and less worn than the exposed chain. While for factory purposes, chain cases are not necessary, they protect chain from dust and grit, and provide constant lubrication. A simple, dust proof case without oil bath is of marked advantage.

Power transmission by means of Diamond Chains offers the logical solution on many short, medium and low speed drives, and the economies are too important for you to neglect.

Write for our treatise "Power Chains and Sprockets". If you desire advice about some special drives, our engineering department will recommend.

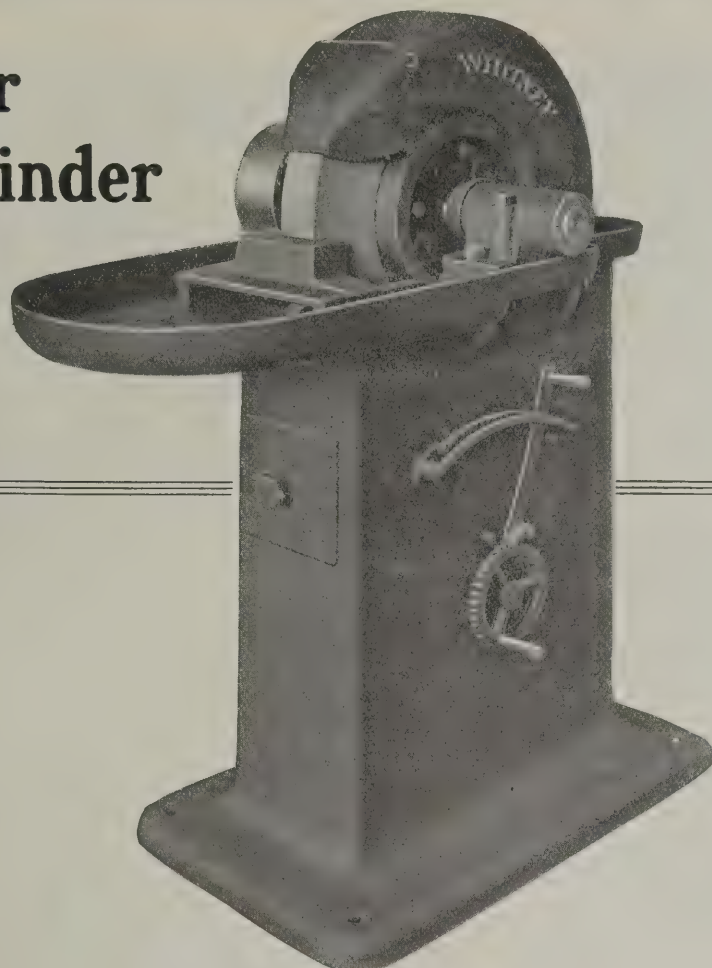
A Water Tool Grinder

"Without a Pump"



The Whitney 20-inch Water Tool Grinder

embraces a number of up-to-date improvements calculated to commend it especially to the favor of discriminating machine tool users. Among the special features of this machine are the following:—

No pump, piping or packed joints to get out of order and leak.

Inside of hood is arranged to catch all water, and keep it from boxes and spindle.

Emery wheel collars are dove-tailed, and fitted with balancing device.

Spindle boxes are self oiling.

Spindle is ground.

Water pan, inside of base, supplies water to the wheel by means of lever, rack and pinion.

Water pan can be easily removed for cleaning.

Machine is simple and cannot get out of order.

Spring lever on side of machine engages with teeth on segment, so that the amount of water supplied to the wheel may be graduated to cover all requirements.

It is impossible for water to escape from pan to the floor.

High Grade—Low Price. Ask for Catalog No. 5.

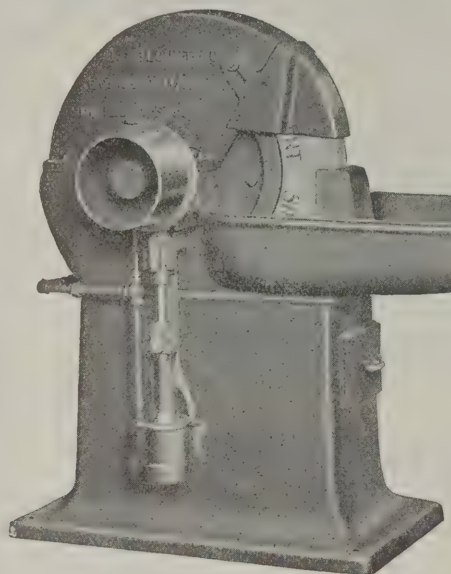
CRANK

A NEW 30-INCH BLOUNT TOOL GRINDING MACHINE

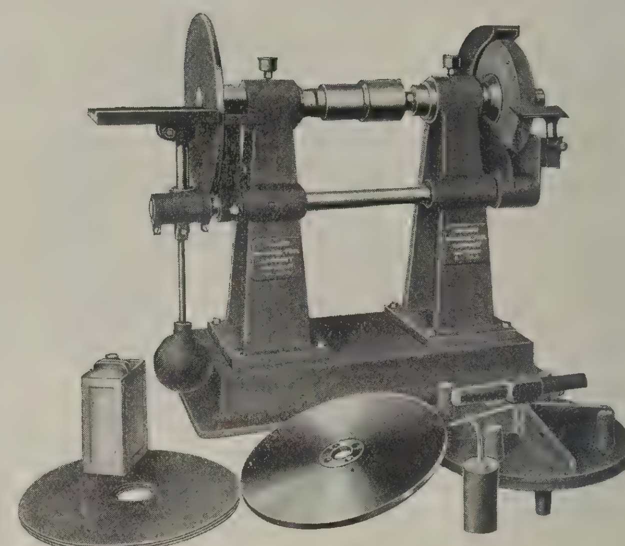
A bigger, heavier, more adaptable machine than our 20-inch Model, with the same successful features—self-oiling bearings throughout, vertical centrifugal pump, guaranteed accuracy, etc.



The supply of water can be regulated to a nicety, pump has no sliding parts to wear out; pump casing extends above the water line and does away with leakage without troublesome packing; other advantages we shall be glad to demonstrate.

Built in quantities—Sold at a moderate price.

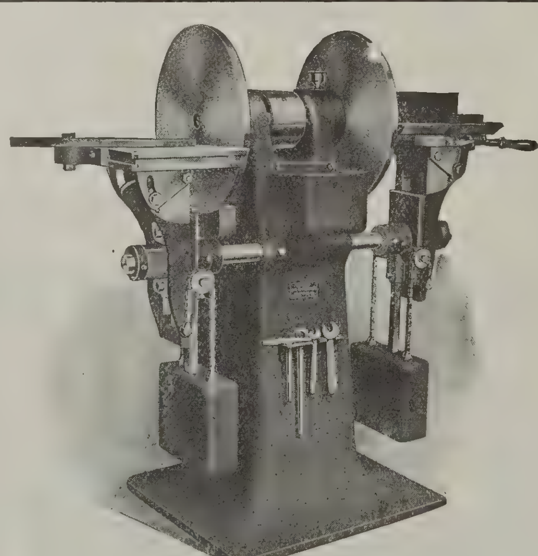
J. G. BLOUNT COMPANY
Everett, Mass., U. S. A.



Note Distance Between Journals
on the Sellew Combination Disc Grinder

See how long we have made the spindle in proportion to the diameter of the disc, and consider how greatly this reduces wear on the journals, eliminates vibration and thereby insures good work. Other advantages are the adjustable support which permits the operator to work at the front as well as the side of the wheel, the Self-oiling Journals, Ball Thrust Bearings and general rigidity of the machine. *Send for full details.*

Sellew Machine Tool Company
Pawtucket, R. I.



A Dependable Grinder
Every user commends the Rowbottom for its perfectly balanced spindle.

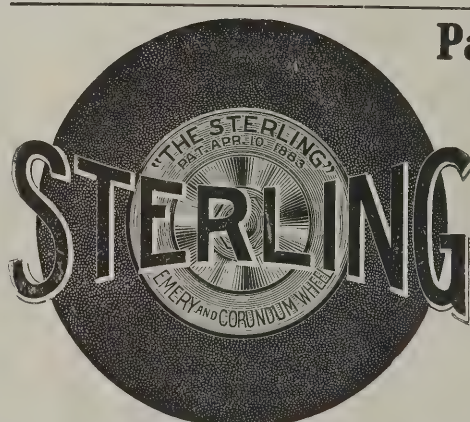
There's no danger of a Rowbottom Disc Grinder getting out of alignment, and no trouble with those easy running Hess-Bright Ball Bearings.

Convenient, too—no time lost placing discs, or adjusting tables.

With an easy running machine, that runs perfectly true, you can always count on **rapid** and **accurate** work. Think what that means.

Special Circular and Prices on request.

THE ROWBOTTOM MACHINE CO.
WATERVILLE, CONN., U. S. A.



Pay More—Get More

Price is relative. You get what you pay for—no more —when you buy grinding wheels, or anything else. Sterling Wheels cost more, are worth more. Would you pay the price in the beginning and save in the end?

Then write us.

BEST BY TEST

The line of machines of which the one shown is representative is the "ULTIMATE" in the floor grinder field.

THEY HAVE:—

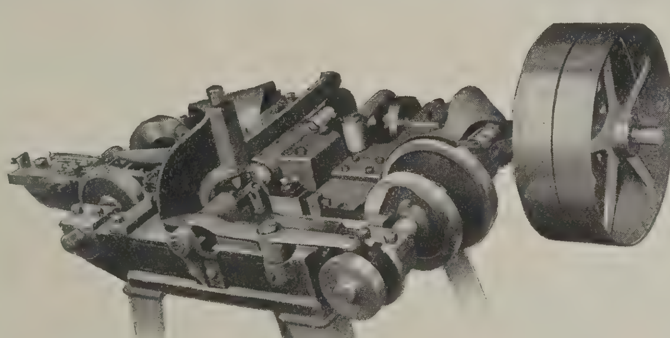
Long Bearings.
Heavy Spindles.
Great Power Capacity.
Heavy Parts Throughout
Best Materials.
Best Workmanship.
Jigged Dimensions Throughout.

THEY ARE:—

Not cheaper but better.
Not light but heavy.
Not short lived.
Best by test.
In stock ready to ship.
Capable of doing the heaviest work.
Guaranteed to be as represented.

These floor grinders are built in 6 sizes, one of which is sure to suit you. There are some manufacturers who try to sell the grinders of their own make from THE SAFETY catalogue and reputation. Beware of these people or you will get STUNG. Give us an opportunity to prove any or all of the above.

The Safety Emery Wheel Co., Springfield, Ohio



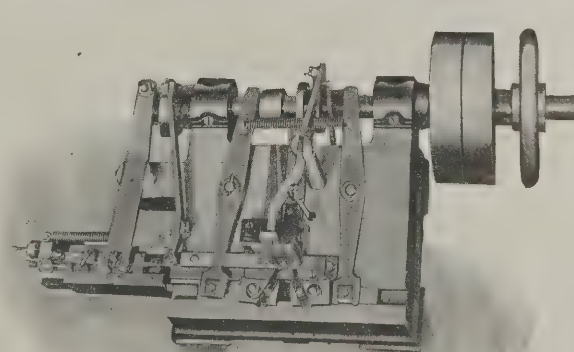
The Profit on Articles Made of Wire

depends largely on the machines used to make them. The experience of our customers shows the necessity of being able to manufacture the article **quickly** so as to keep up with orders.

We build machines that will form and make any special article, of any shape, or size of wire, rapidly, accurately and at a production cost so low that the profit is high.

There is the experience of fifteen years of building wire working machinery back of our machines, and our expert knowledge of conditions is at your service.

Latest Catalogue shows a great variety of wire work handled on our machines and we shall be glad to estimate on your blue prints or samples.

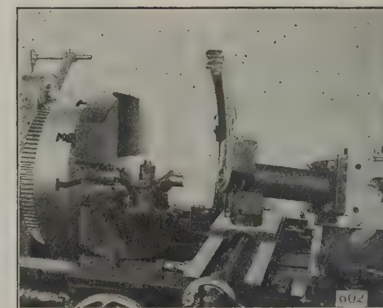


AUTOMATIC MACHINE COMPANY, Bridgeport, Conn.

AGENTS—Alfred H. Schutte, Schuchardt & Schutte, C. W. Burton, Griffiths & Co., of London, England. Marshall & Huschart Machinery Co., of Chicago, Ill., and Motch & Merryweather Machinery Co., of Cleveland, O.

An example of the range of work handled by Gisholt Turret Lathes.

The rough steel pinion is first held in heavy scroll chuck, with jaws fitted to it, and the hole finished. It is afterwards held on an angle plate, centered as shown and the trunnions finished by box tools in turret.



THE GISHOLT PRINCIPLE

Probably every manufacturer recognizes that Gisholt Machines must have merit. But not all manufacturers have tested the Gisholt Principle as applied to their own problems of production.

To those who must reduce the cost and better the quality of their boring, turning and facing work upon medium and heavy castings and forgings, sound judgment suggests a fair consideration of Gisholt Machines.

You can know in advance and without cost whether the Gisholt Principle will apply to your work or not. Twenty-five years of testing Gisholt machines in finishing an infinite variety of parts have taught us what the result will be under specific circumstances.

A corps of trained production engineers, real specialists of long experience, are applying their knowledge to the working out of most intricate problems in chucking and bar work for interested inquirers and customers, prospective or actual. To such of these as have work of the Gisholt type, the results secured are highly gratifying.

It costs you nothing to avail yourself of information which may lead to a definite increase in your production.

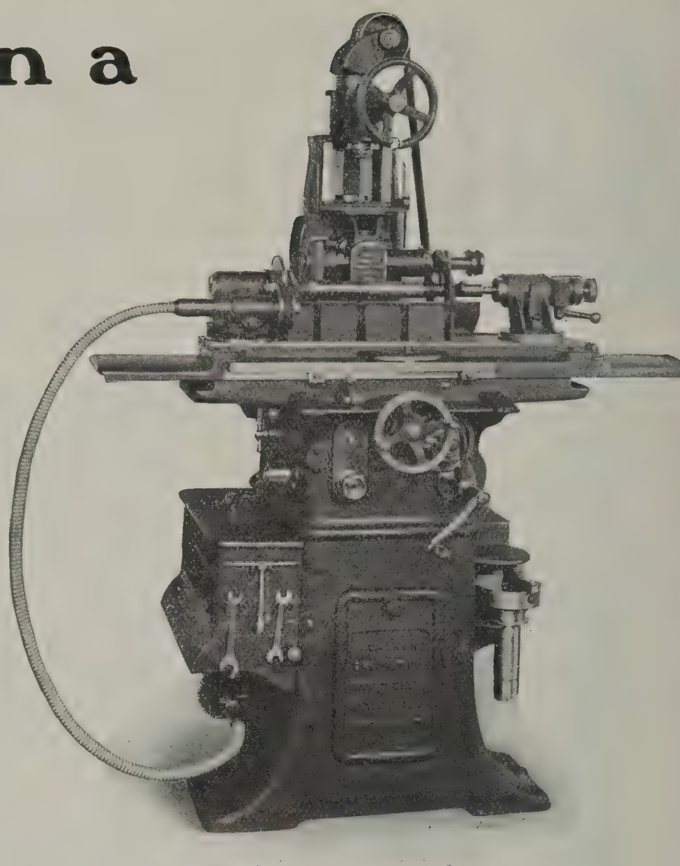
The Coates in a New Role

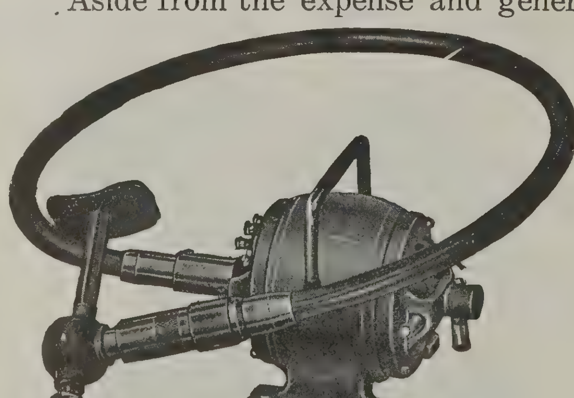


Here's a new application of Coates Flexible Shafts that we want to push home, especially as it is right in the line of machine tool building. The photograph shows the new Walker Grinding Machine, on which Coates Flexible Shaft has been used to drive the work spindle of the machine.

This is an entirely new departure in machine tool operation, embracing the following practical advantages: First, the use of the Coates Shaft keeps the machine a unit, no overhead belt being needed, as the drive is secured by running the "Coates Flexible" from the driving shaft at the base of the machine to the end of the work spindle. This permits motor driven machines to be moved to any position without taking into consideration the numerous overhead belts ordinarily employed on grinding machinery.

Then as the table of a Universal Grinding Machine is used in various angles, the position of the driving head is continually changing, a constant source of trouble if an overhead belt were employed—the Coates Shaft Drive takes care of this feature perfectly.

Aside from the expense and general awkwardness of an off-set drum and driving belt for the work spindle there is an element of vibration present which is detrimental to good grinding. By using the Coates Shaft System of driving this vibration is eliminated, and the operation of the work spindle is smooth and entirely free from shake or jar.



It will pay you to consider the possibilities of applying Coates Shafts to your propositions, whether for grinding machinery or special machinery of any kind. We will be glad to go into the matter at length with you, if you will write us.

COATES CLIPPER MFG. COMPANY

WORCESTER, MASS.

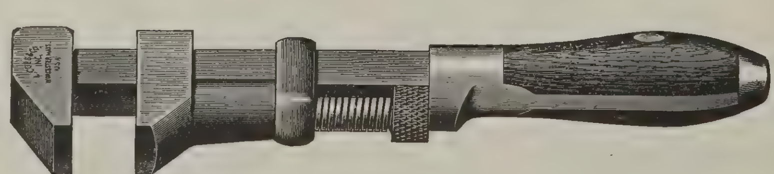
Safe to buy, to Sell and to Use— "COES"—

The Wrench You Can Always Depend On

GET a grip with the "Coes" and the nut must come; pipe the handle six feet if necessary and throw your weight into the balance—"Coes" is the wrench for service, and its 30% greater strength will stand almost any abuse.

Every "Coes" wrench is a wrench of known quality. Sixteen inspections guarantee that quality to maker, dealer and user, insuring maximum service in the hands of apprentice and experienced workman alike.

There is a "Coes" wrench for every service—sizes range from the 4-inch "Steel Handle" wrench to the 72-inch Key Model for the heaviest construction and railroad work.



For more strength, good service and long wear you are safe in trying "Coes".

The Trained Man Has Money

He Can Always Pay His Bills

With the **untrained** man all is different. His wages at the best are small and uncertain. At the end of the month he often finds the pocketbook empty, with the landlord, grocer, butcher, baker, and other tradesmen clamoring for their money. The only difference between the man with ability to command a large salary and your ability is special training—I. C. S. Training.

The International Correspondence Schools have had 20 years' experience in qualifying men for larger salaries and more congenial occupations. It makes no difference how long hours you have to work, or how little schooling you have had, the I. C. S. can train you in your spare time, right in your own home, at small cost.

There is nothing remarkable about it. Simply mark X on the attached coupon opposite the occupation you are interested in, sign your name and address, mail it. In reply you will receive information how you, too, can earn enough money to enjoy every comfort of the man higher up. This is your opportunity to become a trained man, and you will make a great mistake if you fail to grasp this opportunity.

Mark and Mail the Coupon TODAY—NOW!

International Correspondence Schools

Box 980, SCRANTON, PA.

Please explain, without further obligation on my part, how I can qualify for a larger salary and advancement in the position, trade, or profession before which I have marked **X**.

Street and No. ____________________

City __________ *State* __________

Present Occupation ____________________

Our Engineer's report proves that hardly half of the power we generate ever reaches our machines for useful work. Think of it, gentlemen, nearly 50% of what we pay for power goes to run the line shafting, belts, idlers, etc.

The Production Manager's investigation shows that without buying a single new machine, but by simply rearranging the ones we have so that the material will pass directly from one operation to another, we will not only lower the manufacturing cost of our product, but speed up production so that we can meet the demands of the Sales Department.

Here are the Purchasing Agent's specifications, guarantees and prices on motors from the leading electrical manufacturers and after carefully considering them all it seems that the Fort Wayne line fills our particular requirements better than any other. Their prices are right; their service in the way of engineering advice and deliveries is not surpassed, and their customers have all told us there is no better concern in the country to deal with. Let's 'phone for their salesman.

A TRIAL SHIPMENT

Gentlemen:—

Received your Electric Drill and find it very satisfactory. I enclose check for same, and would like you to ship me two more Drills at once.

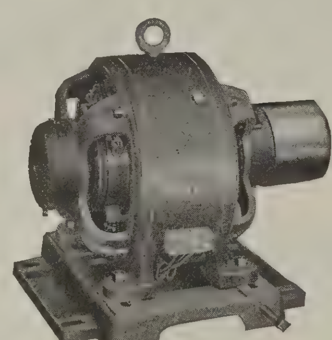
Yours very truly,

We can meet your requirements with a Trial Shipment. Try a Temco Drill and you will want no other.

THE TEMCO ELECTRIC MOTOR CO.
99 Sugar Street LEIPSIC, OHIO, U. S. A.

ROTHMOTORS

are noted for their fine speed adjustments; sparkless commutation; high all-day efficiency; and low maintenance cost—an ideal machine-tool motor. Our grinders and polishers also have many points of superiority.



Write for descriptive bulletins.

"Everything in Blowers and Exhausters"

"Buffalo" Pressure Blowers

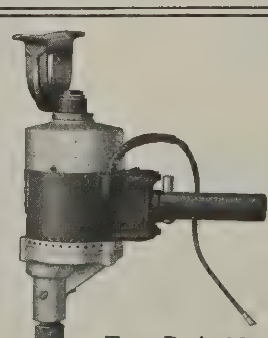
Steam Pulley Electric

Intended for pressures up to 16 oz. Every blower built a little better and stronger than would seem necessary, and tested before shipment. Complete line in stock. The entire fan wheel and shaft can be taken out simply by unbolting one of the side plates. The solid peripheral shell prevents leakage along line of highest pressure.

Catalog No. 178-L 0 on request.

Buffalo Forge Co.-Buffalo, N.Y.

New York Pittsburg Chicago St. Louis Denver



Type D. A. 00 Universal Drill

The PANAMA CANAL is a stupendous undertaking and the work is most exacting. DEPENDABLE EQUIPMENT which will give with long continuous service, the greatest output in the least time at the lowest cost is desirable.

That's why so large a number of our "HARD SERVICE" (portable) ELECTRICALLY operated DRILLS and REAMERS are being employed there day after day in drilling and reaming operations.

Have you read our Pamphlet "REDUCING PRODUCTION COSTS and MANUFACTURING EXPENSES"? Write for it and our Bulletin No. 22, detailing our varied selection of Types, Sizes, etc., of "HARD SERVICE" (portable) ELECTRICALLY operated DRILLS and REAMERS for all classes of work.

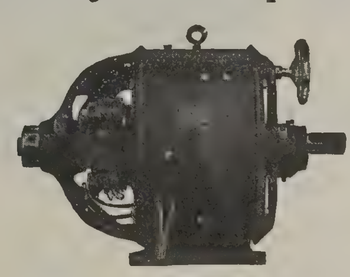
Reliance Adjustable Speed Motors



The Ideal Drive for your Machine Tools

These motors give you all the advantages to be obtained with other motors, plus really accurate speed adjustment over ranges as great as 1 to 10. The changes in speed are smooth and gradual—no steps —no jumps. You get the right speed with ample power for every operation on all kinds of work.

Reliance Adjustable Speed Motors can be installed on the ordinary two wire direct current circuit. No electrical controller—no complicated wiring necessary.

Write for our folder 10-M. It tells all about Reliance Motors and explains why they will make your machines do more work.

We can also furnish Reliance Constant Speed Motors for either A. C. or D. C. circuits.

Reliance Electric & Engineering Co.
1056 IVANHOE ROAD CLEVELAND, OHIO

JESSOP'S "ARK" HIGH SPEED STEEL

Has an Unexcelled Record. ARK. **Note the Following Facts.**

In turning 100 railway car wheel tires, Jessop's "Ark" High Speed Steel has the record of losing less steel, due to grinding, than any other make.

The actual amount of steel ground off the tool in turning 100 wheels was 3 ounces. This is an unrivalled performance in steel economy.

We have a large stock of Carbon Tool Steel and High Speed Steel. Write for Catalogue.

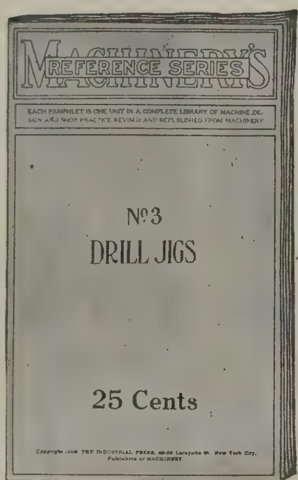
BUFFALO, N. Y., U. S. A.

Ten 25-cent Books for Toolmakers and Tool Designers



TOOLMAKING and tool designing are becoming more and more important with the growth of interchangeable manufacturing methods. The day of the all-around machinist may have passed, but the all-around toolmaker has taken his place. The toolmaker is the star among mechanics. In no trade are skill, judgment and training of higher value than in his. The tool designers and manufacturing experts of tomorrow are the toolmakers who show their ability today. The ablest men always come from the ranks. The best informed men have the first chance, other things being equal. In the toolmaking trade, as in life, growth is impossible without increase of knowledge. Do you want to increase your ability as a toolmaker and designer? These books can help, and exactly along the practical lines that mean results in the day's work.

A CHRISTMAS SUGGESTION

Give a set of these books to some toolmaker you know, especially some young fellow lining up for his future. Maybe you can tell her what these books may mean to him later, in knowledge, skill and earning power. If she gets that right, she will buy him the books and would do it if the cost were ten times $2.25. Real happiness is measured out to human kind in small, infrequent doses. The largest of these come at Christmastide. Take yours, brother.

CONTENTS

No. 3—DRILL JIGS.—Contents: Elementary Principles of Drill Jigs—Drilling Jig Plates—Examples of Drill Jigs—Dimensions of Standard Jig Bushings—Using Jigs to Best Advantage.

KNOWLEDGE vs. GUESS
Gas Heating Apparatus or the Other Kind

You demand precision in your tools and other apparatus, why not in heating appliances? You demand accuracy of product in other departments, why not when hardening and tempering? The first and biggest step toward this end is the installation of heating apparatus in which the control and regulation of heat is positive. Know the amount of heat you need; know that you get it—and the rest of the process becomes a matter of routine.

"American" Gas Furnaces

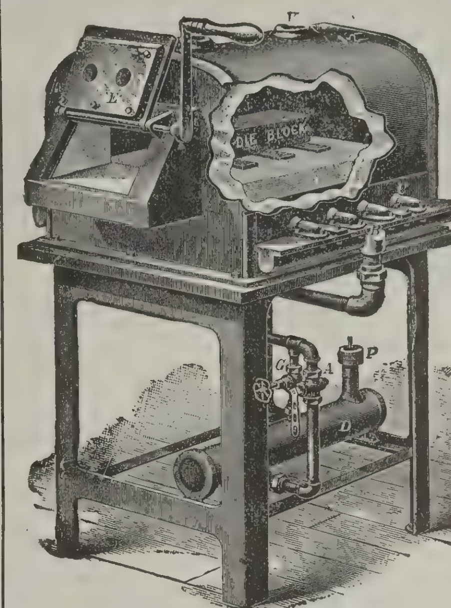
afford absolute even heat distribution and control. Made for all classes of hardening, tempering and annealing.

With our **Heat Regulator and Controller** the temperature can be regulated to within five degrees Fahrenheit.

Write for the complete catalog.

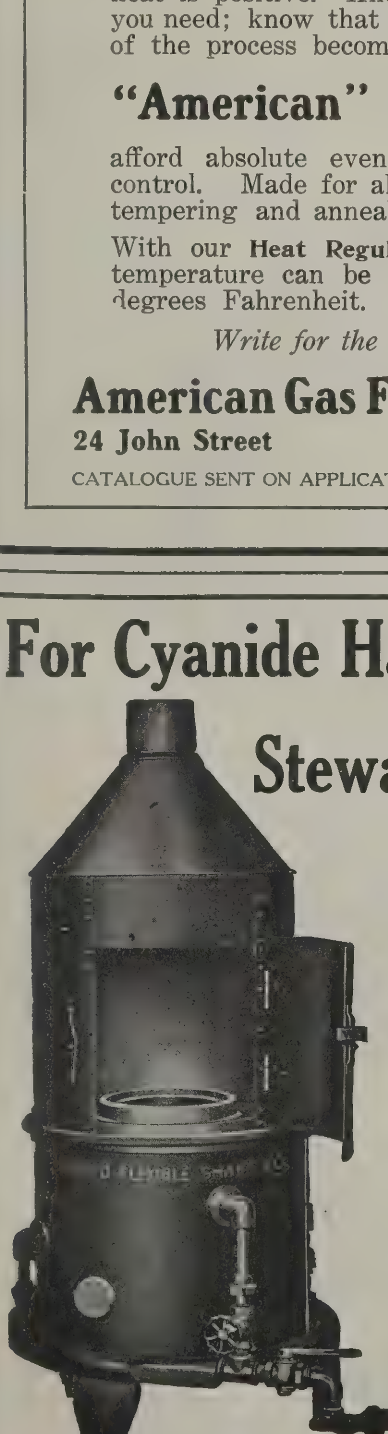
American Gas Furnace Company
24 John Street NEW YORK, U. S. A.

CATALOGUE SENT ON APPLICATION.



Our **No. 1 Oven Furnace** is a popular size for Hardening and Annealing, replacing the "muffle furnace" because of the more direct action of the heat and the presence in the heating chamber of the products of combustion, which prevent oxidation. Muffles exclude these products and are filled with heated air, which promotes oxidation. Let us send you more information on this subject.

For Cyanide Hardening



This
Stewart No. 10

furnace is quite a bit in advance of anything else offered for the purpose.

Bank note engravers, makers of engraved plates, transfer rolls, cutters, dies, springs, chains, etc., where a hard surface without great depth of case is required, find this furnace especially good.

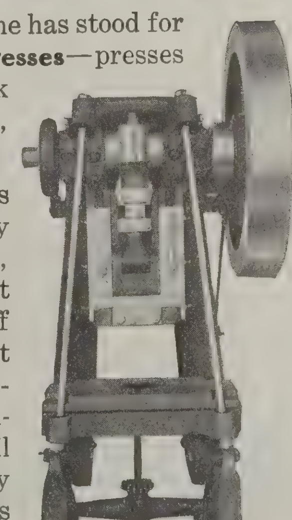
The extreme depth of case can be obtained in 17 to 20 minutes. The cyanide may be brought to a hardening heat in 40 minutes, beginning with a cold furnace.

Write for complete specifications and large general catalogue of furnaces.

Chicago Flexible Shaft Co.
149 La Salle Ave. CHICAGO, ILL.

SWAINE

For forty years that name has stood for **dependable power presses**—presses that for speed, good work and operating economy, are second to none.



The Inclinable Press shown, combines many time-saving features, including a shaft that can be hand turned off centers and the dies set without stopping flywheel; a clutch that cannot be "thrown in" until crank is turned back by hand; two locking points in flywheel, giving instant engagement of clutch—and a host of other features.

We make so many different Presses it takes a 200-page Catalogue to describe them—Sent on request.

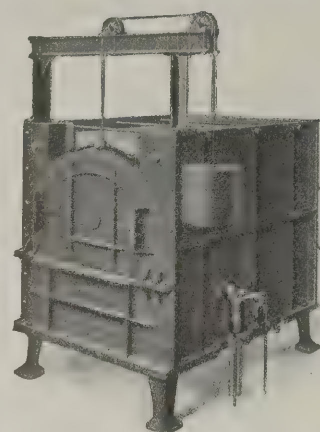
LARGEST PRESS BUILDERS IN THE WEST



Heat Treatment of Steel is An Art

The operations of annealing, hardening and tempering are the most important, the most delicate and the most difficult of all the manipulations to which steel is subject. The ways of performing these operations are all-important. You have to use modern methods, the right type of furnace, to get modern results. Wherever installed, **Tate-Jones Furnaces** have proven most economical and efficient—in the test of daily service.

Let us send our Booklet "Heat Treating of Steel"—a treatise on the art, and a catalog.

HOSKINS

Give Your Tool Hardener the Right Equipment

—an equipment in keeping with the importance of his work. Every time he fails to harden a tool properly, you not only lose the value of the steel, his and the tool maker's time, but you *hold up the job* the tool was meant to do. Don't blame the tool hardener. Instead, help him to

Eliminate Uncertainty

from his work and at the same time save yourself the cost of his unsuccessful efforts. Give him an equipment that will enable him to do good work *all the time,*— to make *every tool* as accurate and long-lived as it is possible to make it. Take advantage of the greater earning capacity and the decreased production costs that only *efficient tools* make possible.

Hoskins Electric Furnaces

—in the hands of competent tool hardeners in many of the country's largest plants—are producing tools that are truly remarkable for their efficiency. They are setting new standards of work and life for cutters, taps, dies, drills and many other tools and are really showing the enormous possibilities in modern tool steels, *when properly heat-treated.*

The item at the left will show you the kind of work the Hoskins Furnace is doing and the little square at the right contains an offer to prove that it is the *right equipment for your tool hardener.*

Two and A Half Years of Better Tools

—is the record of the Hoskins Electric Furnace shown above.

This furnace was installed more than two and a half years ago in one of the tool rooms of a large and well known manufacturer of conveying machinery.

The result was a very great increase in the efficiency of the tools.

So great was this increase in efficiency that it was soon found advisable and economical to ship tools, to be hardened in this Hoskins Furnace, from the Company's two other plants located in far distant cities.

Let Us Give You Proof

- without obligation—that the Hoskins Furnace can produce better tools for you. Let us harden several of your tools, free—to be tested by you against similar tools hardened by your present or any other method. Ask us today for further details and our "Bulletin 10."

21" with Tilting Table

That Tilting Table on "Modern" Drills

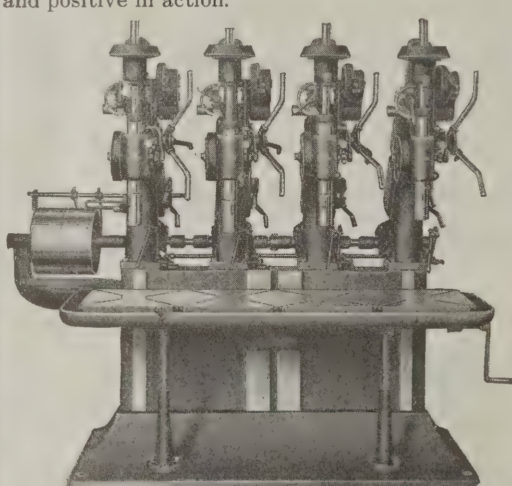
is a wonderful time saver. Take such work as cylinder castings for example, which require drilling at different angles—you can tilt this table **at any angle up to 90 degrees** and place the piece so that it can be worked to advantage. The square spindle you see, through the crown gear, eliminates friction—another good feature. Note, also, how conveniently we have located every lever and handle—no back-breaking reaches, and no stopping work to change from belt driven to back gears—throw a lever and "presto" the change is made. This and our 20" drill are both built to **save time** and they **do it.** *Send for Circular and Prices.*

FRONTIER IRON WORKS, Buffalo, N. Y.

ALSO BUILDERS OF ROYAL POWER SAWS.

Big Savings in Time
Big Increase in Power

And this means an increased output—made possible by our All Geared Gang Drills. No cone or feed belts. No slipping and loss of time. Each spindle has eight changes, each of Geared Speeds and Geared Feeds, all controlled by levers conveniently reached from front of machine. Easy to operate and positive in action.



Our 20 inch gang here shown drives a 1" high speed twist drill at rate of 8 inches per minute in cast iron and 4 inches per minute in mild steel. Built in two to sixspindles and also in 24" and 26" sizes.

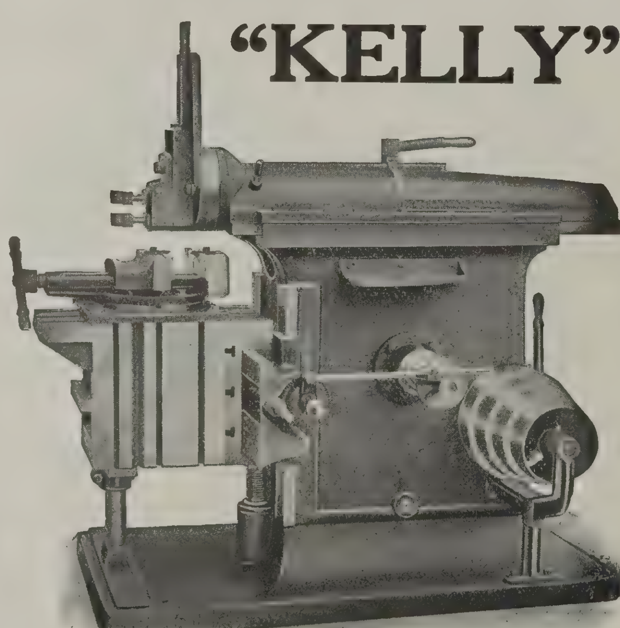
"KELLY"



The essential point about shaper work is ACCURACY. Caliper any job done on a "Kelly"—you'll find it true to a **hair line.**

This can't be said of **all** shapers, but its a "Kelly" trait that carries weight. The catalogue goes into details—construction, attachments, sizes—may we mail a copy?

THE R. A. KELLY COMPANY, Xenia, O.

Power—Direct to Drills

Drill power transmission is a great problem. The best drilling machine is the one which transmits the most power **direct to the drills.** Usually the belted types of machines waste a large part of the power they convey to the drills, due mostly to slippage, the breaking of belts, and friction.

With Taylor & Fenn Drilling Machines the power is applied by means of gears and silent chain.

No slippage. No breaking of belts. No needless friction. And best of all, the feed can be operated only, when the spindle is in motion.

Ask for catalogue.

Mr. George E. Abbott,
Abbott Ball Company,
Hartford, Conn.

Dear Sir:-

Replying to your request, we have no hesitancy in recommending the Abbott Ball Tumbling System. We have had it in use from nine to ten months. Its installation has permitted our doing away with an expensive polishing and buffing equipment as well as the high priced labor necessarily involved. We are to-day producing twice the number of parts at half the cost, getting a better finish and doing away with the expense of cleaning polished work of the rouge that naturally collects in creases and corners.

Very truly yours,
HERON MANUFACTURING COMPANY.

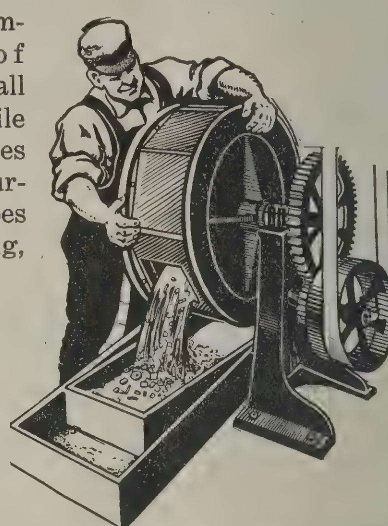
RPH/N

"Twice the Polishing at Half the Cost"

Read this Letter

Two facts stand out prominently in this communication; the character of the work and its fine finish, and that the high-priced labor formerly employed for polishing has been done away with entirely.

The Abbott Burnishing Process, by means of the Abbott Barrel and Abbott Balls is the modern, economical method of polishing small metal parts. While the process does not remove surface metal it does produce a polished surface at a fraction of the cost for hand polishing, no matter whether the work is steel, brass or copper.



Send us samples of your work. We'll finish them free of charge, tell you just how long it took to do it, and what it will cost for an installation in your own plant.

No Valve Troubles if you Use Dudgeon Jacks

In a recent number of a popular "Weekly," a writer on Scientific Management says he saw screw jacks being used in a locomotive shop, at a terrific cost in time, and a dozen hydraulic jacks piled up on the same floor waiting for valve repairs.

THEY WERE NOT DUDGEON JACKS

A condition such as that couldn't arise if Dudgeon Jacks were the equipment. The single valve chamber construction in our Universal Double Pump Plain Jack does away with the cause of valve trouble. It removes all the objectionable complications of valves and passages which heretofore impaired the double pump jack.

Other double pump jacks require three pressure valves and two suction valves (five valves in all) while the Dudgeon Universal has but one pressure valve and two suction valves (three valves in all), and of the suction valves but one is used at a time. Other double pump jacks have three passages between the pressure chamber and the reservoir, each closed by a single valve, the failure of any one rendering the jack inoperative. The Dudgeon Jack has but one passage, containing three valves, any one of which, alone, can perform the functions commonly shared by the three.

Send for the circulars and more details. They will interest you.

Hyatt High Duty Bushing

No loss of power between driving belt and drill point

The Rockford High Duty Drilling Machine will drive a $3\frac{3}{16}$ inch drill through *seven* inches of .40 carbon steel in *one* minute. The power which is supplied by a *six* inch *single* belt is practically all delivered at drill point because *all* bearings are of the Hyatt High Duty Type. The above record could not be made if plain bearings were used.

The Hyatt is a distinctive type of roller bearing—the rollers are flexible steel spirals, which cushion shock, act as oil reservoirs and oil distributors and under all conditions present a line of contact the entire length of the bearing.

Six to eight thousand Hyatt Bushings are made daily.

Write for bulletins 600A and 305—they are both full of information for the maker and user of machine tools.

HYATT ROLLER BEARING CO.
NEWARK, NEW JERSEY

2031 B

Did you read in "Power" where Mr. A. E. Derby practically specifies Cling-Surface?

In his article "Care of Belting in the Factory" in "POWER," Jan. 9, 1912, this gentleman concludes with these specifications for a preparation usable on belts:

"**It should** soften the pulley side of the belt; penetrate the fiber; lubricate and protect the fiber from crumbling; prevent the generation of static electricity.

It should not decompose; be influenced by moisture; dry up; cause the belt to stick to the pulley when idle, as though glued there and when starting pull off the surface and expose the fiber; leave a film on the surface of the belt; contain mineral acids."

Very good. Cling-Surface easily complies and does even more it penetrates and makes the whole belt pliable. It makes the belt absolutely waterproof. Where Cling-Surface is used in the wettest places, in pulp and paper mills, in laundries, and in very humid climates, it proves itself invaluable for waterproofing and preserves against disintegration.

State your troubles today and let us advise. Our literature is ready for your mailing request.

WHY CUT METAL GEARS IN YOUR OWN PLANT?

Metal gear cutting can't be done in short time and at low cost in any shop where the machines must be temporarily rigged up for this work today and for something else tomorrow. Nor can you expect the same accuracy as where the operatives concentrate their entire attention on gear work.

From its beginning, twenty years ago, this company, with a well organized engineering staff, a thoroughly modern shop, and ample capital, has given its attention almost exclusively to gear cutting.

Our service includes designing (when necessary), pattern work, the furnishing of brass, iron or steel castings, forgings, or bar stock as required, and the complete finishing of gears of any standard types.

Our plant contains over 200 special machines, including automatic and engine lathes for turning blanks from bar stock, castings and forgings; milling and hobbing machines for spur, spiral and helical teeth; cutters and planers for blocking out bevel teeth, Gleason generators for cutting bevel gear teeth; grinders for truing up the bores of hardened steel gears, etc. No order is too large, too small, or too difficult. We give you accuracy at low cost and deliver at least as quickly as your own plant. Send blueprints and let us quote on your next rush order.

New Process Pinions are the Strongest Non-Metallic Gears Made

We frankly admit that some kinds of solid metal pinions outlast New Process Pinions, but where prevention of noise and vibration enters into consideration positively no other gears on the market compare with New Process for durability and ultimate satisfactory service. And in almost every instance, a noisy metal to metal gear drive can be **successfully** and **permanently quieted at reasonable expense** by substituting a New Process Pinion for the noisy metal one.

Our new process of treating the rawhide gives it the good qualities of metal without the metallic ring, and only discs blanked from the strongest parts of the hide are used in making gears. These are glued together, dried under heavy hydraulic pressure, the blank faced off and the whole machined just like a solid metal pinion. Hence the rawhide fibers bear end-on against the other gear and being supported by the metal at the sides will stand up without sign of weakness. In fact the teeth wear down to knife edges without stripping or breaking, and are as silent when old as when new.

You would never go back to metal pinions after trying one New Process Pinion on any high speed drive. Their installation not only adds to the comfort of the entire shop force, does much to save time and avoid misunderstandings, but easily repays the expense in reduced breakage of gear teeth and lengthened life of the machines, the latter due to the lessening of vibration.

Your troubles from noisy gear transmission are easily settled and our engineers are at your service. Tell us where you would consider New Process Pinions and we will send literature.

NEW PROCESS IS TO ALL OTHER RAWHIDE AS STEEL IS TO IRON

GEARISMS

Published by the Philadelphia Gear Works
1120 Vine Street, Philadelphia, Pa.

Vol. 1 DECEMBER 1912 No. 3

DEVOTED *to the* INTERESTS *of* GEAR USERS EVERYWHERE
Edited by the Little Gear Man

Over 20 Years Ago

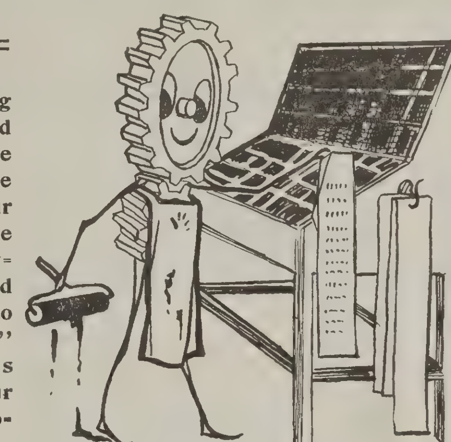
We made the first Philadelphia Gears. They were good gears then; but they are better now, for we have combined experience with theory—and there are kinks that the best mechanics can learn by experience only, as you know. The growth and development of Philadelphia Gears from the beginning of a small business to the occupancy of our own building, with its specially designed machinery and equipment, is an interesting story in itself, and goes to prove that knowledge, experience and square dealing, with a certain necessary amount of push, will win success under any circumstances.

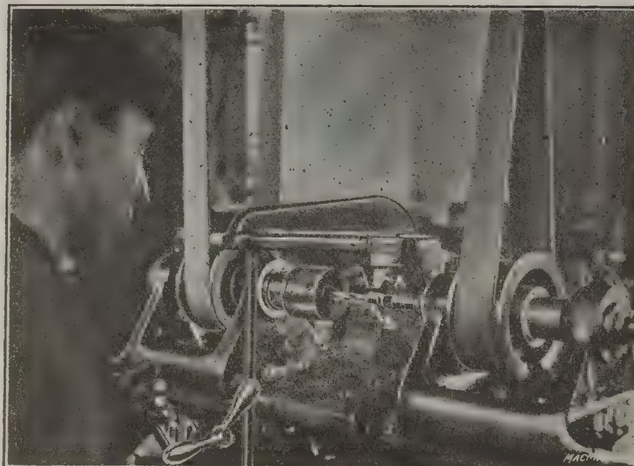
Promptness and square dealing are hobbies with us. We can make *better* gears for you. Try us.

The "Little Gear Man" on Efficiency

The efficiency of a train of gears, or of any other power transmitting mechanism for that matter, is measured by the percentage of the power put into the shaft on which the driving gear is mounted, which is delivered by the shaft on which the driven gear is mounted. In general it may be said that there is no method of transmitting power between two parallel shafts that is more efficient than a pair of well designed and carefully constructed spur gears, working under proper conditions. The highest efficiency is obtainable of course, only at considerable expense. Hence, good judgment is required to decide to what extent refinements in the manufacturing processes of gears are warranted. This judgment comes only by years of experience in the manufacture and use of gearing.

We are getting out leaflets and "flyers" all the time and would like to put you on our mailing list. The catalog, too, showing stock sizes and styles we carry to meet your "rush" requirements should be in your file. Write us today.





Pointing Foster Set Screws

Foster Safety Set Screws are turned from the solid, the hexagonal hole is broached, and then the burrs are carefully drilled from the bottom of the hole, the blank being held in jaws as shown and the point concaved to the correct angle at the same time. In every detail of manufacture Foster Safety Set Screws show fine finish, close accuracy and great strength, as well as safety.

Dependable Safety Set Screws. Try them. Circular?

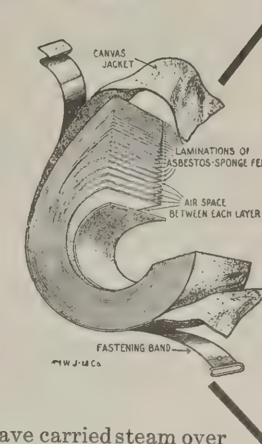
Which Would You Rather Do—Buy Additional Machinery or Protect Your Steam Pipes?

It is remarkable how many leave long systems of steam piping bare or poorly insulated. In plants where such is the case the apparatus receives steam in a state of about 40 per cent efficiency, and oftentimes twice the number of machines are used than would be necessary if the steam pipes were properly insulated with



J-M Asbesto-Sponge Felted
Pipe Covering

Pipes insulated with this covering have carried steam over 5000 feet with practically no loss. Unlike other pipe coverings, it will not crack, break or lose its insulating value through vibration or rough usage. It has been found in perfect condition after more than 15 years' service on underground pipes.

If you value economical plant operation, write our nearest branch today for Sample and Catalog No. 100.

DIXON'S
Graphite Lubricants

Dixon's Flake Graphite No. 1.
This is the standard size of Dixon's Ticonderoga Flake Graphite, and is recommended for general lubricating requirements.

Dixon's Flake Graphite No. 2.
A more finely ground graphite than No. 1, though of the same stock. This is adapted to close-fitting bearings and delicate mechanism.

Dixon's Flake Graphite No. 635.
This is a selected grade of Dixon's Ticonderoga Flake Graphite ground even finer than the No. 2 Flake. It is widely used in stationary gas engines. This grade of graphite is also used on type-setting machinery.

Dixon's Waterproof Graphite Grease.
A strongly adhesive grease of heavy body; cannot be washed off by fresh, salt, alkaline or acid water. Especially adapted for wire rope, gears, slides, chains, elevator-ways, mining and quarrying machinery, and generally on machinery exposed to water or the weather.

Write for "Graphite as a Lubricant" and free sample 80 C.

The Elgin Tool Works
ELGIN, ILL.

HIGH GRADE DIAMOND POINTED TOOLS

For dressing and shaping Emery, Carborundum and all abrasive wheels. Carefully selected diamonds possessing both hardness and toughness and securely mounted with the grain in the proper relation to the wheel, make all the difference in the world with the wearing qualities of Diamond Tools. These features are guaranteed. Write for Circular and prices.

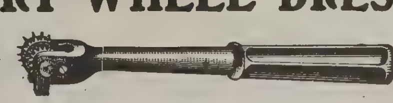
KEEN EDGE DIAMOND TOOL WORKS
242 Griswold Street Detroit, Mich., U. S. A.

Grinding Machines

Different Styles and Sizes for Floor and Bench.

EMERY WHEEL DRESSERS

No. 1 For Regular Shop Use



No. 2 For Large Wheels

These Dressers in connection with our Cutters make a most powerful and efficient tool especially our No. 2 which is made proportionately larger and stronger for large wheels.

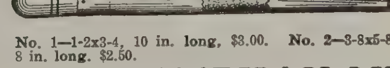
CUTTERS

We make the regular "Huntington" (pattern) Paragon Cutter and Roughing Cutter for Dresser No. 1, and the "Huntington" (pattern) and Roughing Cutters for Dresser No. 2.

Let us send you descriptive circular and prices.

GEO. H. CALDER, Lancaster, Pa., U. S. A.

The Star-Carbon Emery Wheel Dresser



No. 1—1-2x3-4, 10 in. long, $3.00. No. 2—3-8x5-8, 8 in. long, $2.50.

The great substitute for the Black Diamond. Has advantages over the Black Diamond for shaping and truing up wheels. Our circular will explain why. Have your dealer furnish one, or order one on ten days' trial.

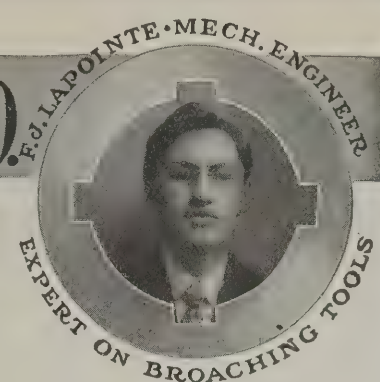
J.N.LAPOINTE CO.



NEW FACTORY
NEW LOCATION

Having moved into our new factory at New London, Conn., the largest, most up-to-date, practically constructed, and most completely equipped plant devoted exclusively to the manufacture of

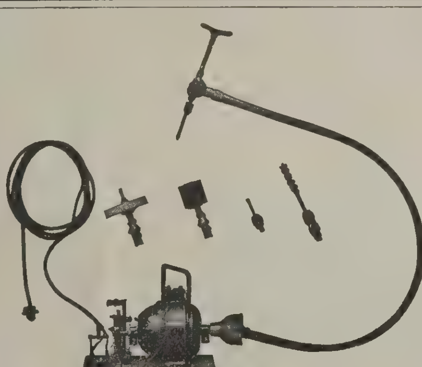
Broaching Machines and Broaching Tools

we are prepared to offer to our friends—both old and new—a service in this particular line of industry that is entirely without equal.

The organization is headed by the originators of the present commercial type of broaching machines and broaching tools, and the staff is made up of men who have become experts in this special line. Added to these are improved machinery, latest methods, facilities for increased production, a stock in trade that cannot fail to assure results. Write us for details.

THE J. N. LAPOINTE CO., New London, Conn., U.S.A.

If It's An Original Stow



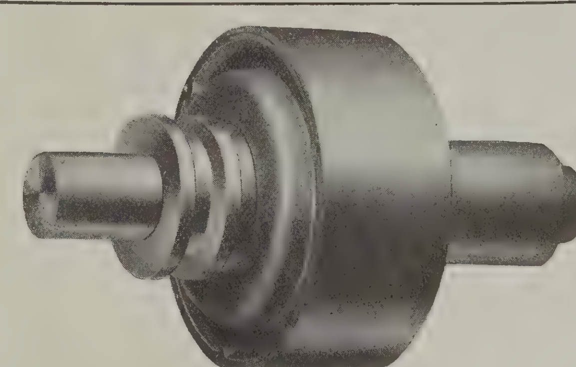
It's A Time Saver

Cut Down the Working Time

and save money with a Stow Portable Flexible Shaft Outfit. Style shown is for light metal drilling, grinding, brushing and polishing. It is completely equipped ready for work as soon as connected to any lamp socket. The motor is a ¼ H.P. "Ready" Electric Motor—a little beauty.

We make Flexible Shaft Outfits for every requirement. Send for Illustrated Catalog.

Stow Flexible Shaft Company
26th and Callowhill Streets, Philadelphia, Pa.



A Clutch You Can't Burn Out

The Cleveland Clutch is designed and made to slip when overloaded—it simply cannot be burned out. It is oil and dust tight; smooth and positive in action; requires no attention and very infrequent oiling; is ideal for use where dust or grit would put other clutches out of business, also in out of the way or hard to reach places.

Specify "Cleveland" when you say "Clutch" in your next machine purchase.

Let us send you the bulletin, showing the few parts, simple action, specifications and price.

The Cleveland Clutch Co.

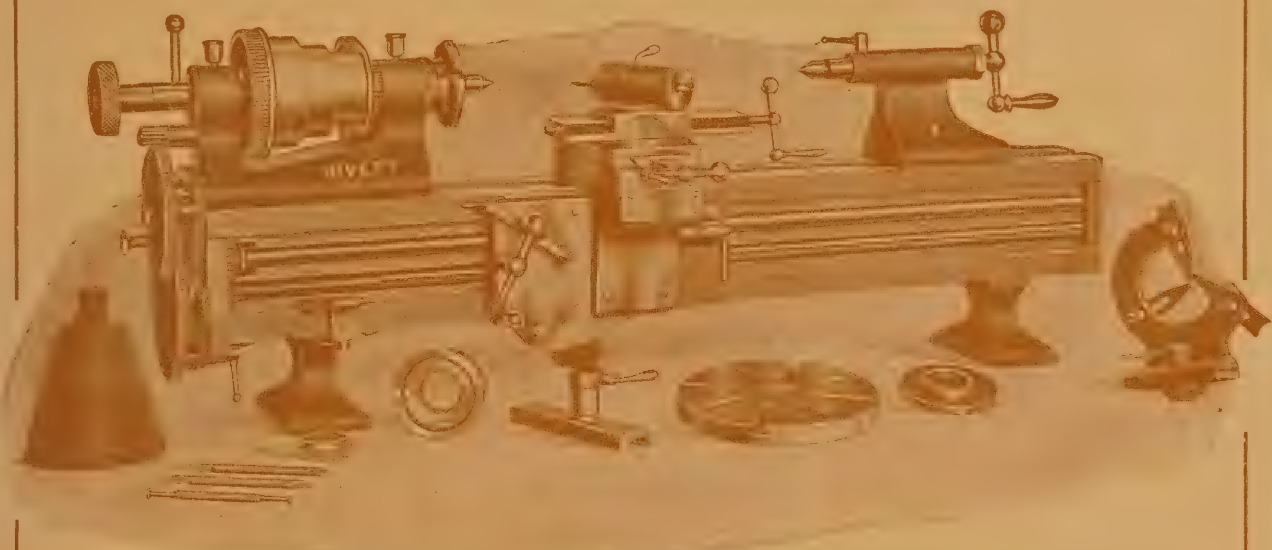
Rivett 8-inch Precision Lathe

The Most Complete Tool

There's almost no limit to the number of operations that may be performed on the 8-inch Rivett equipped with full line of attachments. From plain turning to spiral milling the variety of pieces, taper mills, reamers, counterbores, milling cutters, spiral gears, hobs, taps, etc., that can be made is endless—and the remarkable feature is that much of this work can be produced at a lower cost than by any other tool on the market. There is keen satisfaction, too, in knowing that every operation is correct and accurate, and that any piece can be duplicated absolutely, at any time.



All Rivett Precision Lathes are back geared, which gives them the great range of speeds necessary to turn out work varying from 8-inches to a few thousandths in diameter. Their strength is remarkable—this 8-inch model will take a 1/4-inch cut in tool steel, and a 3/8-inch cut in machinery steel, heavier chips than can be turned with many 16-inch lathes now on the market. Solidity and rigidity in construction make high rates of speed possible and heavy turning easy. Can you find the suggestion toward a solution of some of your problems in these brief paragraphs? Then write us. We'll gladly send the catalog containing complete descriptions of the lathes and their attachments, and showing many examples of everyday production handled on these machines—work which you may never have considered taking to a tool of this type.
